Implications of a comparison of the stratigraphy and depositional environments of the Argana (Morocco) and Fundy (Nova Scotia, Canada) Permian-Jurassic basins

Paul E. Olsen, Dennis V. Kent, Sarah J. Fowell, Roy W. Schlische, Martha O. Withjack & Peter M. Letourneau

Abstract. – The Argana rift basin of Morocco and the Fundy rift basin of the Maritime Provinces of Eastern Canada are on the conjugate margins of the central Atlantic Ocean. In the Late Triassic and Early Jurassic these basins lie at similar paleolatitudes within the same great rift system. A comparison of the depositional- and tectono-stratigraphy reveal strong similarities, much greater that those shared between the Fundy basin and other rifts in eastern North America. Both the Argana and Fundy basins are comprised of four, mostly unconformity-bound, tectonostratigraphic sequences (TS I-IV) probably controlled by pulses of extension: TS I, is Permian in age and the depositional facies of the Argana basin looks more humid than the age equivalent in the Fundy basin and the latter may not be a rift sequence; TS II, is early Late Triassic (Carnian) in age and is the most humid looking facies in both basins; TS III, is late Late Triassic (Norian and Rhaetian) in age and is much more arid in both basins with abundant aeolianites and evaporites; TS IV, is latest Triassic and earliest Jurassic (late Rhaetian - early Hettangian) and shows an increase in the range of variability in climate-sensitive facies - its basal part contains the Triassic-Jurassic boundary an overlying basalt flow sequence and additional fluvial and lacustrine strata on top. The dramatic similarity in both facies and sequence stratigraphy between the Argana and Fundy basins, at least during the Triassic, argues for similar tectonic control, restricted to that latitudinal swath of Pangea, as well as similar paleoclimate.

Résumé. – Implications d’une comparaison de la stratigraphie et des environnements de dépôts des bassins permo-jurassiques d’Argana (Maroc) et du Fundy (Nouvelle-Écosse, Canada)

Le bassin d’Argana au Maroc et le bassin de Fundy des provinces maritimes du Canada, de type rift, sont les marges conjuguées de l’océan Atlantique central. Au Trias supérieur - début Jurassique, ces bassins se trouvaient à des paléolatitudes similaires dans le même système de rift. Une comparaison de la sédimentologie et la tectono-stratigraphie des deux
bassins révèle de grandes similarités, beaucoup plus grandes que celles existantes entre le bassin de Fundy et les autres rifts de l’est de l’Amérique du Nord. Les bassins d’Argana et du Fundy comprennent quatre séquences tectono-stratigraphiques (TS I-IV), la plupart du temps limitées par des discordances et qui sont contrôlées par des poussées en extension: TS I, d’âge permien, les faciès de dépôt du bassin d’Argana paraissent plus humides que leurs équivalents dans le bassin de Fundy qui ne sont probablement pas une séquence de rift; TS II, d’âge triasique inférieur (Carnien), enregistre les faciès les plus humides pour les deux bassins; TS III, d’âge triasique supérieur tardif (Norien et Rhétien), est beaucoup plus aride dans les deux bassins avec des éolianites et des évaporites en abondance; TS IV, d’âge triasique à début jurassique (Rhétien tardif - début Hettangien), montre une augmentation de l’intervalle de variabilité des faciès sensibles au climat. sa partie basale contient la limite Trias-Jurassique surmontée par des coulées basaltiques et des couches supplémentaires fluviales et lacustres au sommet. La très grande similarité des faciès et des séquences stratigraphiques entre les bassins d’Argana et du Fundy, au moins durant le Trias, plaide en faveur d’un contrôle tectonique similaire, limité à une bande latitudinale du Pangea, mais aussi à des paléoclimats similaires.

### 1. Introduction

Of the numerous Central Atlantic Margin (CAM) rift basins that developed during the initial rifting of Pangea (e.g., Olsen, 1997), the Argana and Fundy basins provide an especially useful comparison because they developed on nearly opposite sides of the Atlantic continental conjugate margins and within a relatively narrow latitudinal swath (fig. 1). This paper outlines the remarkable overall similarities and highlights the
important differences of the stratigraphy and environments of the two basins in an effort to separate regional from local controls on the evolution of the basins' stratigraphic section.

2. Tectonostratigraphic Sequences

Recently, Olsen (1997) divided the generalized stratigraphy of CAM basins into four tectonostratigraphic sequences (fig. 2). Each tectonostratigraphic sequence is bounded by unconformities, at least in the up-dip direction. Their basal contacts onlap onto the older tectonostratigraphic sequences, or basement, and their upper contacts tend to show offlap in the up-dip direction. Typically there is a change in the environmental milieu across the tectonostratigraphic sequence boundaries, and there can be a significant hiatus at the unconformity. In contrast to typical marine sequences boundaries, we assume these tectonostratigraphic sequence boundaries do not have any eustatic component. Instead they may be the expression of the largest-scale synrift tectonic and/or climatic events.

Basé sur Kent et al. (1995), Muttoni et al. (1996) et Kent et Muttoni (2000).
This scheme for tectonostratigraphic subdivisions of CAM basins was strongly influenced by new insights gained by the authors during field work in Morocco during 1992, 1994, and 1999 and from the literature, especially Tixeront (1973). The tectonostratigraphic sequences for the Argana and Fundy basin are shown in Figure 3, which summarizes a major revision of the stratigraphy of the Fundy basin (Olsen et al., 2000) and a modification of the tectonostratigraphy of the Argana basin presented by Olsen (1997). Below we compare and contrast the four tectonostratigraphic sequences in the Argana and Fundy basins.

3. Tectonostratigraphic Sequence I (TS I)

The Ikakern Formation (Brown, 1980; T1 of Tixeront, 1973) and Honeycomb Point Formation (Nadon and Middleton, 1984) comprise TS I in the Argana and Fundy basins respectively (fig. 3). When Olsen (1997) first placed these units in TS I of the these basins, the tectonostratigraphic unit was assumed to be Middle Triassic (Anisian) in age, based on admittedly scant and contradictory data. However, descriptions of undoubted examples of the hammer-headed amphibian Diplocaulus from the Ikakern Formation (Jalil and Dutuit, 1996), as well as our preliminary paleomagnetic data from the Honeycomb Point Formation, showing reversed polarity and shallow inclinations, suggest a Permian age (Kent et al., 2000).

Although there is evidence of deposition of the Ikakern Formation in an extensional basin setting (Medina, 1991), no such evidence has been described for the Honeycomb Point Formation. In fact, the latter is almost lithologically identical to the apparently coeval Cap aux Meules Formation (Brisbois, 1981; Tanczyk, 1988) of the non-rift Magdalen basin in the Gulf of St. Lawrence, Canada (350 km to the northeast), which seems to have developed as a very broad sag. The Honeycomb Point Formation could just be an outlier of the Cap aux Meules Formation, fortuitously preserved within the Fundy rift basin. This needs to be tested by a search for fault-related growth features in the Honeycomb Point Formation itself.

The strata of TS I in the Argana and Fundy basins show considerable differences in apparent climatic milieu. The Ikakern Formation consists of a generally fining up package with relatively dense bioturbation by burrows and roots, and evidence of eolian deposits is lacking (A. Tourani, pers comm., 1999), suggesting a relatively humid environment. The Honeycomb Point Formation, on the other hand, does not seem to fine upward, bioturbation is relatively less common, and eolian sandstones are very prominent upward, suggesting a much more arid environment. This relatively dramatic difference in climatic milieu contrasts with the three succeeding pairs of Triassic-Jurassic tectonostratigraphic sequences, which are very similar to each other.

4. Tectonostratigraphic Sequence II

TS II overlies TS I unconformably in both the Argana and Fundy basins. Outcrops of the angular unconformity are present in both basins (Tixeront, 1973; Olsen, 1997). In the Argana basin TS II is comprised of the Timesgadiouine Formation (Brown, 1980; T 3-5 of Tixeront, 1973) which consists of fluvial and lacustrine clastic rocks with an especially well developed cyclical lacustrine sequence in the lower part of the Irohaline Member (T5) (fig. 3). The outcropping strata of TS II in the Fundy basin belongs to the Wolfville Formation (revised, fig. 3), which is nearly entirely fluvial. However, subsurface data (Withjack et al., 1995) suggest that there are lacustrine equivalents to the Wolfville deeper within the basin as long suggested by Brown (Wade et al., 1996).
Biostratigraphically, the Timesgadiouine and the Wolfville formations are very similar. Both units contain relatively abundant vertebrate remains indicating inclusion in the Economian (revised) and Sanfordian Land Vertebrate Age (LVA) faunachrons of Huber et al. (1993) and Lucas and Huber (2000). Most notably, in both basins, the lower part of TS II produces capitosaurs (Aglegal and
“Economy” members), and the upper part produces metoposaur amphibians (Irohaline and “Evangeline” members) (Jalil, 1996; Baird, 1986; Olsen et al., 1989). The Economian and Sanfordian LVA are thought to correlate with the Julian and Tuvalian of the Carnian (Huber et al., 1993; Olsen et al., 2000), a correlation supported by palynoflorules from both basins (Fowell, 1994).

In the Fundy basin, the oldest strata of the Wolfville Formation (“Economy member”) has two known beds of eolian sandstone, in what is otherwise an intensely bioturbated sandstone and clast-supported conglomerate (Skilliter, 1996; Olsen 1997). The bulk of the Wolfville (“Evangeline member” and equivalents), lacks eolian deposits, but continues the pattern of intensely bioturbated sandstone and clast-supported conglomerate with weakly to moderately developed soil caliches suggesting deposition in semi-humid environments (Olsen, 1997; Tanner, 1996). Although, the lacustrine strata of the Timesgadiouine Formation of the Argana basin, have abundant desiccation features in the shallow-water portions of sedimentary cycles, they lack evaporites or the sandpatch fabric characteristics of more arid lacustrine deposits. Thus, the overall relatively humid climatic milieu of the Timesgadiouine and Wolfville Formation appear to be very similar.

5. Tectonostratigraphic Sequence III (TS III)

An angular unconformity at least locally separates TS II and TS III in the Argana and Fundy basins. In the Argana basin, the upper Timesgadiouine Formation truncated by a gentle angular unconformity (<5°: fig. 4)), at least locally (Tixeront, 1973; Olsen, 1997), and then overlain by the Bigoudine Formation of TS III (Brown, 1980; T 6-8 of Tixeront, 1973). Similarly, in some areas of the Fundy basin, a profound angular unconformity (~90°) separates the Wolfville Formation of TS II from the Blomidon Formation (redefined) of TS III (fig. 4). In other areas there may be a gentle angular unconformity, or none at all, but existing outcrops do not permit resolution of this uncertainty.

Remarkably similar sequences characterize TS III in the Argana and Fundy basins. In both basins, the basal unit of TS III, Tadrat Ouadou Member (Argana) and “Red Head member” (Fundy), are comprised of fluvial conglomerate and sandstone and prominent eolian sandstones (Olsen, 1997; Benauiss, 1999; Hubert and Mertz, 1984). In both cases, the eolian strata are interbedded with laterally continuous red mudstones that become dominant upward into the succeeding members. These are cyclical red, evaporite-

bearing, mudstones and sandstones with a characteristic style of sequences termed sand-patch cycles (Smoot and Olsen, 1988; Olsen et al., 1989; Olsen, 1997; Tourani et al., 1999). The main lithological differences between the two TS III sequences in the two basins, are in the lower Bigoudine Formation. The Tadrat Ouadou Member contains at least some interbeds of halite.

Fig. 5. – Comparison of boundary sections, lower TS IV, in the Argana and Fundy basins with sample positions. The position of the Triassic-Jurassic boundary is based on the samples shown in bold (from Fowell and Traverse, 1995; and Fowell, pers. comm., 2000).

The overlying Sidi Mansour and lower Hasseine members have several laterally continuous gray and black shale beds. Neither of these are known from the homotaxial portions of the Fundy basin ("Red Head" and lower "White Water members") (fig. 3). However, the bulk of the Hasseine and "White Water" members are nearly identical homotaxial ("Red Head" and conchostracans have been found, indicating only a Late Triassic age for most of the formation. Gray and black units in the Sidi Mansour and lower Hasseine members have produced a number of palynological assemblages, some being dated as Carnian (Tourani et al., 2000) and some as Norian (Fowell, pers. comm.; Olsen, 1997). Detailed descriptions of these assemblages have not been published and it is unclear whether the different assignments reflect real differences in age or differences in interpretation. Very preliminary and incomplete paleomagnetic study of the lower Bigoudine Formation, does allow for the lower part of the formation to be older than the lower Blomidon Formation. The age of the uppermost Bigoudine is earliest Jurassic as constrained by palynology (Fowell, pers. comm.; Olsen, 1997), but we regard the palyniferous beds as belonging to TS IV.

Better age control is available for the Blomidon Formation, which has produced the procolophonid Hypsognathus (Sues et al., 2000), and track assemblages (Olsen et al., 1989; Olsen et al., 2000), indicating inclusion of nearly all of the Formation in the Cliftonian LVA, which conventionally indicates a middle Norian through Rhaetian age (Huber et al., 1993; Lucas and Huber, 2000). The top of the formation ("Partridge Island member") is Early Jurassic, again based on palynology (Fowell et al., 1994; Fowell and Traverse, 1995) (fig. 5).

Kent and Olsen (2000) described the magnetostratigraphy of the entire Blomidon Formation based on continuous core (Getty Mines GAV 77-3) and this allows detailed correlation with the Newark basin (fig. 6), confirming the paleontological correlations. Some part of at least one polarity zone (E22r) and possible parts of upper E22n or lower E23n are missing from the upper part of the Blomidon core suggesting a minor hiatus. This may be evidence for an unconformity between TS III and TS IV in the upper Blomidon Formation and suggests placement of the beds of the uppermost "White Water member" and the "Partridge Island member" in TS IV. Likewise we believe that the uppermost Bigoudine Formation belongs in TS IV, although there is no known physical evidence for an unconformity. Indeed, the exposed strata could be sufficiently down-dip to be within the zone of the correlative conformity (as in most of the exposed Newark basin). We stress that the Triassic-Jurassic boundary is represented in the upper Blomidon, and there is no evidence that the unconformity is within the boundary section.

6. Tectonostratigraphic Sequence IV (TS IV)

TS IV consists of the uppermost portions of the Bigoudine and Blomidon formations which is succeeded by basalt flows and overlying minor carbonates and red clastic rocks (fig. 3). The uppermost Bigoudine and Blomidon formations (upper "White Water" and "Partridge Island members") both begin with sand-patch-bearing red mudstones and sandstone, but within a few meters of the overlying basalts are a very distinctive suite of thin red, gray and black mudstone beds (fig. 5), which are generally palyniferous (barring local metamorphism from the basalt) and contain the Triassic-Jurassic boundary. They are termed the "Partridge Island member" in the Fundy basin. A parallel nomenclatural designation might be useful for the homotaxial portion of the Bigoudine Formation.

The Argana Basalt (it of Tixeront, 1973) and the North Mountain Basalt conformably overlie the uppermost Bigoudine and Blomidon formations in the Argana and
Fig. 6. – Time and geography matrix for selected CAM basins in North America and Morocco. The gray curved lines represent lines of equal paleolatitude fixed by the Newark basin paleomagnetic record. Note that the Argana basin "present latitude" is given within as if still attached to the North American plate and with present day North American coordinates. Note that polarity zones shown as bars spanning half a column are represented by only one sample with that polarity. Data from Kent and Olsen (1997, 2000) and LeTourneau (1999).

Fundy basins, respectively (fig. 2). Both basalt formations consists of two major flows and several thin interbedded and overlying flows which have, for the most part high-titanium, quartz-normative type tholeiitic chemistry (Puffer, 1992, pers. comm., 2000; Pe Piper et al., 1992; Dostal and Greenough (1992); Bertrand (1982); Ait Chayeb et al. (1998). The North Mountain Basalt has yielded U-Pb ages of 202±1 Ma, in good agreement with other Eastern North American basalts (Hodych and Dunning, 1992). The Argana Basalt has not yet to be dated by more modern methods, but has produced a K/Ar date of 196±17 Ma (Manspeizer et al., 1978), with the large errors probably due to alteration. This age is consistent with the ages of the eastern North American basalts as well as similar basalts from Morocco (Sebai et al., 1991).

Overlying the basalt flow formations in both basins are thin carbonate-dominated units succeeded by predominately red clastic rocks. In the Argana basin, the Ameskroud Formation (Hofmann et al., 1998; Tourani et al., 2000), contains a basal carbonate and black shale sequence, followed by predominately red and brown mudstones and sandstones with a few thin gray beds (Tixeront, 1973). In the Fundy basin, the McCoy Brook Formation contains a basal carbonate-rich sequence of two white, green, purple, and red lake level cycles (Scots Bay Member) (De Wet and Hubert, 1989; Tanner, 1996) and overlying predominately red clastic rocks, including some very local eolian sandstones (Hubert and Mertz, 1984). These produce a relatively rich vertebrate assemblages (Olsen et al., 1987), comprising the type Wassonian LVA of Hettangian and possibly younger age (Lucas and Huber, 2000). Strata of TS IV are unconformably overlain by post-rift Early Jurassic conglomerates and marine strata in the Argana basin, and Quaternary strata in the Fundy basin.

Placing the Argana and Fundy basin sections into a geography by time matrix with other CAM basin sections, calibrated by the Newark basin standard time scale (Kent and Olsen, 1999; Olsen and Kent, 1999), helps separate the regional from local patterns (fig. 6). Perhaps the most dramatic regional pattern, described in detail elsewhere (Olsen, 1997; Olsen and Kent, 1999; Kent and Olsen, 2000), is the strong arid-to-the-north trend, coupled with an overall increase in aridity through the Late Triassic (Olsen, 1997; Olsen and Kent, 1999; Kent and Olsen, 2000). Particularly important is the relative similarity between the paleoclimate significant coeval facies between the latitudinally close Argana and Fundy basin, and the dissimilarity to coeval strata farther south, which were deposited under more humid climate conditions. During the Late Triassic, the outline of the eastern North American plate was oriented azimuthally not too different than today, although it was obviously located much further south (fig. 1). In the reconstruction of Kent et al. (1995) (fig. 1), the Argana basin was located only two degrees south of the Fundy basin, even though separated by about 7° degrees of longitude. There is now considerable evidence that the Argana and Fundy basins translated north through the Late Triassic through a strong latitudinal climate gradient, not appreciably different than that seen today in Africa north of the equator (Kent and Olsen, 2000). As the basins drifted north they passed through successively more arid climate belts. Therefore, the large change in climate-sensitive facies from relatively humid to arid across the TS II - TS III unconformity in both basins reflects the significant duration of the hiatus, during which the basins moved northward, into the arid belt. In addition, the apparent greater wetness indicated by the lower Bigoudine Formation (i.e., the gray and black shales), could be explained by the slightly more southern position of the Argana basin relative to the Fundy, and by the slightly older age of the lower Bigoudine Formation relative to the lower Blomidon, or both.
The synchronous change to more humid conditions in TS IV over all of the CAM basins (Olsen, 1997), however, clearly requires a different kind of hypothesis. This is because, at a minimum, the basins south of Europe and Greenland should have been getting more arid as Pangea continued its northward drift. The fact that the climate trend is reversed requires a widening of the humid belts in the latest Triassic and earliest Jurassic (Rhaetian - Hettangian). This still occurred within the context of a prominent trend to more arid facies towards the north within North America (Hubert and Mertz, 1984; LeTourneau and Huber, 2000). However, this more humid episode is not reflected globally, with very large regions (e.g. southern Africa, western United States) behaving as might be expected from nearly constant zonality (e.g. southern Africa, western United States). One hypothesis that would explain this pattern would be an increase in humidity related to the invasion of marine waters into much of the northern CAM rifting zone, giving a more proximal source of moisture for the northeast trade winds. Evidence for this within CAM basins includes the distribution of salt in various other basins in Morocco, where it is relatively well constrained in age and stratigraphically (Et Touhami, 2000). This would have affected the more southern CAM basins, including the Fundy and Argana basins, but the effect would not likely have extended far beyond the rifting zone.

Early TS IV time was also one of extreme biological turnover, and may be linked to the apparent climate change. In this hypothesis, the absence of correlative climate change elsewhere could reflect the brevity of the episode and a concomitant lack of temporal resolution outside the CAM basins. A bolide impact (Olsen et al., 1987; Fowell et al., 1994; Olsen, 1997), massive volcanism (i.e., Central Atlantic Margin Province, CAMP; Courtillot, 1996; Marzoli et al., 1999; Olsen, 1999), and sea level changes (Hallam, 1990; Hallam and Wignall, 1997) have been proposed as an origin of the mass extinction at the Triassic-Jurassic boundary. However, because the climate change began before the mass extinctions, a single bolide impact or the biotic changes themselves cannot be the cause of the increase in apparent wetness in the CAM basins.

An additional possibility for the origin of the apparent increase in wetness within TS IV could be an increase in basin asymmetry, caused by an increase in extension rate, itself linked to the origin of the CAMP basalts (Schlische and Olsen, 1990). In this view all the apparent indicators of humidity would increase because of sediment and water focusing along the axis in a relatively more asymmetrical rift. It is not very obvious how to discriminate this hypothesis from one of real climate change. However, evaporites decrease and bioturbation increases in even the most shallow-water deposits in the more southern CAM basins (e.g., Newark basin), but increase into TS IV in Moroccan basins. These changes occurred at the same time as the amplitude of lake-level cyclicity increased in TSIV. This argues that increased overall humidity during TS IV time, perhaps related to the entry of marine waters in the more northern rifts, is at least part of the explanation.

A different kind of explanation is needed again for the observed differences between the Argana and Fundy representatives of TS I, which clearly do not fit into any simple pattern as seen in the Triassic-Jurassic strata. The difference between TS I in the two basins could be due to either an increase in the climatic gradient or to apparent non-zonal climate change caused by plate movement from a Pangea B (fig. 1B) to a to Pangea A (fig. 1C-D) configuration. An enhanced climatic gradient in the Permian, relative to the Late Triassic could be due to an real climatic change or could be due to the rotation of Pangea (Pangea A configuration) clockwise in the Permian. This would dramatically increase the basins' separation in latitude from about 2° (Late Triassic) to over 6° (Permian), but without a change in the actual distance between them (fig. 1C, D) or the actual climate gradient. We favor this rotation model because paleomagnetic
results from the Honeycomb Point and Cap aux Meules Fm. does suggest a relative counter clockwise rotation for North America, from the Permian into the Triassic. Paleomagnetic data (currently under study) is needed from the Ikakern Formation to resolve whether Pangea A or B was in place by the median Permian, and to test the rotation hypothesis. Alternately, the Honeycomb Point and Cap aux Meules formations might not the same age as the Ikakern, given the lack of biostratigraphic control, although the Permain age of the Cap aux Meules Formation is not in doubt, which leaves the same basic problem.

A distinctive feature of TS II - IV in the Argana and Fundy basins is their similar overall depositional stratigraphies. Each has a fluvial or very shallow water lacustrine base, a lacustrine middle and a very shallow water lacustrine or fluvial top (fig. 7) corresponding to what Schlische and Olsen (1990) calls a "tripartite sequence" common to many rifts (Lambiase, 1990). The "basin" filling model of Schlische and Olsen (1990) explains this tripartite sequence as a consequence of the evolving geometry of the sediment surface and basin outlet that need not invoke any changes in extension rate or climate. However, a pulse of extension could produce the same result (Olsen, 1997).

For a continental basin, a single pulse of extension, in the absence of other extensional pulses, would follow the basic "basin filling model "outlined by Schlische and Olsen (1989) and elaborated on by Contreras et al., (1997) as follows. The onset of extension creates a half graben. If there is sufficient sediment supply, initially a fluvial sequence is deposited basin-wide, because the depositional surface remains at the lowest outlet of the basin. As the basin widens through time so does the sediment surface, and without a compensatory increase in total sediment flux, the accumulation rate declines and the basin becomes hydrologically closed with an onset of rapidly deepening lacustrine conditions. As sedimentation continues, the basin floor widens and eventually, without any increase in the volume of water entering the basin, the water depth must decline as well. As subsidence decreases during the waning phase of the extensional pulse, the basin fills to its lowest outlet, leading eventually to basin-wide fluvial conditions and to erosion along the axis of the basin as the basin outlet itself is eroded.

In CAM basins, with the possible exception of TS I and TS IV, the full tripartite sequence was generally not realized within each tectonostratigraphic sequence. Olsen (1997) and Schlische (2000) ascribe the origin of Tectonostratigraphic Sequences II - IV to significant pulses of extension spread over 30 million years. Each pulse increased basin asymmetry. Erosion occurred on exposed previously deposited syn-rift strata in the hanging wall, while focusing of sediment and water occurred towards the depositional axis of the basin resulting in a very rapid onset of lacustrine conditions. Thus, each pulse of extension would produce a single tripartite sequence with TS III and IV each having a truncated basal fluvial portion. In this scenario, unconformities between TS II and III and between TS III and IV in the Argana and Fundy basins are a result of reduced deposition, non-deposition, and/or erosion during the waning phases of each of the major pulses or during the time between pulses.

A striking similarity between the Argana and Fundy basins that differentiates them from some of the more southern CAM basins, such as the Newark basin, is the relatively long hiatus between TS II and III that omits all or most of the Conewagian LVA in the Argana and Fundy basins (fig. 6). This difference could be due to the much greater amount of postrift erosion in the Newark basin compared to the Argana and Fundy basins. The present-day surface of deeply eroded basins, such as the Newark basin, places outcrops (and cores) closer to the expected position of the correlative conformities of the tectonostratigraphic sequence boundaries. Because of the offlapping nature of the older strata and the onlapping form of the younger strata, a much more complete section would be
present at or close to the surface in the basins with deeper post rift erosion. A prediction of this hypothesis is that the duration of the hiatus represented by the TS II - TS III unconformity should greatly decrease towards the interior of the basins, which are accessible only by drilling and geophysics. A similar explanation can be used for the TS III - TS IV hiatus in the Fundy basin. This may not be true for the TS I - TS II unconformity, because the tectonic regime in which TS I was deposited in the two basins may have been completely different.

The diagram shows the time scale with average water depth and climate changes.
One consequence of this view of these tectonostratigraphic sequences is that the fluvial and eolian strata at the base of TS III (e.g., Red Head beds in the Fundy basin) are marginal facies of more basinward lacustrine strata and should not be the same age either throughout a single basin or between basins, such as the Argana and Fundy, and it should be nearly or completely absent at the basin depocenter. This is different from the upward shallowing pattern in TS II - IV, which does reflect a historical change in the hydrological basin as a consequence of basin widening and filling.

It is important to note that the comparison between the Argana and Fundy basins and their component tectonostratigraphic sequences forces a distinction to be made between arid and humid facies developing under different climate milieux and fluvial versus lacustrine conditions deposited under different hydrologic conditions in the basin. The two are not interdependent. Thus, we have relatively arid fluvial and eolian strata (Tadrat Ouadou and Red Head members of TS III), relatively arid lacustrine strata (Sidi Mansour, Hasseine, and "White Water" members), relatively humid fluvial strata (parts of the Aglegal and Irohaline members and Wolfville Formation of TS II), and relatively humid lacustrine strata (lower Irohaline Member and seismically imaged strata of Wolfville Formation). Thus, the combinations of various facies produced in the stratigraphic evolution of the Argana and Fundy basins reflect the interplay of tectonics as (extensional pulses), which created accommodation space, the evolution of that space because of sediment infilling, and changes in climate controlled by plate motion and true global change (fig. 7).

**Acknowledgments**

We are grateful for support of this research (to PEO) from the Lamont-Doherty Earth Observatory Climate Center and the US National Science Foundation (EAR-98-04851) to DVK and PEO and (EAR-9814475) to PEO and Hans Sues (Royal Ontario Museum). We especially thank the LDEO Climate Center for funding the most recent fieldwork (1999) in Morocco and ONAREP for logistical support during that visit. I warmly thank Mohammed Et Touhami, Mrabet, El Mostaine, Aît Brahim (of ONAREP), Driss Ouarhache, Naima Benouiss, and Abdel Ilah Tourani for stimulating discussions on Moroccan rifts and as well as pleasant company during the visit of PEO and RWS. We are especially grateful to Mohammed Et Touhami for coordinating the 1999 field work. Previous field work (1994) in Morocco was supported by the US National Science Foundation (ATM 93-17227) of PEO and DVK. We thank Neil Shubin, Annika Johansson, Philip Huber, and Driss Nabil, for their help during that visit, and Hans Sues for discussions on the vertebrate faunas.

**Fig. 7.** - Qualitative conceptual diagram showing the main influences on the development of the Argana and Fundy basins. Ages are largely based on correlation with the Newark basin. Water depth for TS II of Fundy basin based interpretation of seismic lines. Abbreviations under water depth and climate are: F, fluvial; FL, fluvial and shallow water lacustrine; SL, shallow lacustrine; DL, deep perennial lake; +E, arid with abundant eolianites; -E, less arid with rare eolianites; -W, slightly humid with much bioturbation; +W, more humid. Note that these classes are meant to reflect the average state. We have not attempted to show high-frequency fluctuations between extremes.

**Fig. 7.** - Diagramme conceptuel qualitatif montrant les principales influences sur le développement des bassins d'Argana et de Fundy. Les âges sont en grande partie basés sur la corrélation avec le bassin de Newark. La profondeur de l'eau pour la TS II du bassin de Fundy est basée sur l'interprétation des lignes sismiques. Les abréviations concernant la profondeur de l'eau et le climat sont: F, fluvial; FL, fluvial et lacustre peu profond; SL, lacustre peu profond; DL, lac profond, permanent; +E, aride avec eolianites abondantes; - E, moins aride avec eolianites rares; - W, légèrement humide avec beaucoup de bioturbation; +W, plus humide. Notez que ces classes sont destinées à refléter l'état moyen. Nous n'avons pas essayé de montrer des fluctuations à haute fréquence entre les extrémités.
