1 Approaches to High-Dimensional Covariance and Precision Matrix Estimation

1.1 Introduction

Large covariance and precision (inverse covariance) matrix estimations have become fundamental problems in multivariate analysis, which find applications in many fields, ranging from economics, finance to biology, social networks, and health sciences. When the dimension of the covariance matrix is large, the estimation problem is generally challenging. It is well-known that the sample covariance based on the observed data is singular when the dimension is larger than the sample size. In addition, the aggregation of huge amount of estimation errors can make considerable adverse impacts on the estimation accuracy. Therefore, estimating large covariance and precision matrices has attracted rapidly growing research attentions in the past decade. Many regularized methods have been developed: Bickel and Levina (2008); El Karoui (2008); Friedman et al. (2008); Fryzlewicz (2013); Han et al. (2012); Lam and Fan (2009); Ledoit and Wolf (2003); Pourahmadi (2013); Ravikumar et al. (2011b); Xue and Zou (2012), among others.

One of the commonly used approaches to estimating large matrices is to assume the covariance matrix to be sparse, that is, many off-diagonal components are either zero or nearly so. This effectively reduces the total number of parameters to estimate. However, such a sparsity assumption is restrictive in many applications. For example, financial returns depend on the common risk factors, housing prices depend on the economic health, gene expressions can be stimulated by cytokines. Moreover, in many applications, it is more natural to assume that the precision matrix is sparse instead (e.g., in Gaussian graphical models).

In this chapter, we introduce several recent developments on estimating large covariance and precision matrices without assuming the covariance matrix to be sparse. One of the selected approaches assumes the precision matrix to be sparse and applies column-wise penalization for estimations. This method efficiently estimates the precision matrix in Gaussian graphical models. The other method is based on high-dimensional factor analysis. Both methods will be discussed in Sections 2 and 3, and are computationally more efficient than the existing ones based on penalized maximum likelihood estimation. We present several
applications of these methods, including graph estimation for gene expression data, and several financial applications. In particular, we shall see that estimating covariance matrices of high-dimensional asset excess returns plays a central role in applications of portfolio allocations and in risk managements.

In Section 4, we provide a detailed description of the so-called “factor pricing model”, which is one of the most fundamental results in finance. It postulates how financial returns are related to market risks, and has many important practical applications, including portfolio selection, fund performance evaluation, and corporate budgeting. In the model, the excess returns can be represented by a factor model. We shall also study a problem of testing “mean-variance efficiency”. In such a testing problem, most of the existing methods are based on the Wald statistic, which have two main difficulties when the number of assets is large. First, the Wald statistic depends on estimating a large inverse covariance matrix, which is a challenging problem in the data-rich environment. Secondly, it suffers from a lower power in a high-dimensional-low-sample-size situation. To address the problem, we introduce a new test, called “power enhancement test”, which aims to enhance the power of the usual Wald test.

In Section 5, we will present recent developments of efficient estimations in panel data models. As we shall illustrate, the usual principal components method for estimating the factor models is not statistically efficient since it treats the idiosyncratic errors to be both cross-sectionally independent and homoskedastic. In contrast, using a consistent high-dimensional precision covariance estimator can potentially improve the estimation efficiency. We shall conclude in Section 6.

Throughout the paper, we shall use $\|A\|_2$ and $\|A\|_F$ as the operator and Frobenius norms of a matrix $A$. We use $\|v\|$ to denote the Euclidean norm of a vector $v$.

### 1.2 Covariance Estimation via Factor Models

Suppose we observe a set of stationary data $\{Y_t\}_{t=1}^T$, where each $Y_t = (Y_{1,t}, ..., Y_{N,t})'$ is a high-dimensional vector; here $T$ and $N$ respectively denote the sample size and the dimension. We aim to estimate the covariance matrix of $Y_t$: $\Sigma = \text{Cov}(Y_t)$, and its inverse $\Sigma^{-1}$, which are assumed to be independent of $t$. This section introduces a method of estimating $\Sigma$ and its inverse via factor analysis. In many applications, the cross-sectional units often depend on a few common factors. Fan et al. (2008) tackled the covariance estimation problem by considering the following factor model:

$$Y_{it} = b_i'f_t + u_{it}.$$  \hspace{1cm} (1.1)

Here $Y_{it}$ is the observed response for the $i$th ($i = 1, ..., N$) individual at time $t = 1, ..., T$; $b_i$ is a vector of factor loadings; $f_t$ is a $K \times 1$ vector of common factors, and $u_{it}$ is the error term, usually called idiosyncratic component, uncorrelated with $f_t$. In fact, factor analysis has long been employed in financial studies, where $Y_{it}$ often represents the excess returns of the $i$th asset (or stock) on time $t$. The literature includes, for instance, Campbell et al. (1997), Chamberlain and Rothschild (1983), Fama and French (1992). It is also commonly used in macroeconomics for forecasting diffusion index (e.g., Stock and Watson (2002)).

The factor model (1.1) can be put in a matrix form as

$$Y_t = Bf_t + u_t.$$ \hspace{1cm} (1.2)
where $\mathbf{B} = (b_1, ..., b_N)'$ and $\mathbf{u}_t = (u_{1t}, ..., u_{Nt})'$. We are interested in $\Sigma$, the $N \times N$ covariance matrix of $\mathbf{Y}_t$, and its inverse $\Theta = \Sigma^{-1}$, which are assumed to be time-invariant. Under model (1.1), $\Sigma$ is given by

$$
\Sigma = \mathbf{B} \text{Cov}(\mathbf{f}_t) \mathbf{B}' + \Sigma_u,
$$

(1.3)

where $\Sigma_u = (\sigma_{u,ij})_{N \times N}$ is the covariance matrix of $\mathbf{u}_t$. Estimating the covariance matrix $\Sigma_u$ of the idiosyncratic components $\{\mathbf{u}_t\}$ is also important for statistical inferences. For example, it is needed for large sample inference of the unknown factors and their loadings and for testing the capital asset pricing model (Sentana 2009).

In the decomposition (1.3), it is natural to consider the conditional sparsity: given the common factors, most of the remaining outcomes are mutually weakly correlated. This gives rise to the approximate factor model (e.g., Chamberlain and Rothschild (1983)), in which $\Sigma_u$ is a sparse covariance but not necessarily diagonal, and for some $q \in (0, 1)$,

$$
m_N = \max_{i \leq N} \sum_{j \leq N} |\sigma_{u,ij}|^q
$$

(1.4)

does not grow too fast as $N \to \infty$. When $q = 0$, $m_N$ measures the maximum number of non-zero components in each row.

We would like to emphasize that model (1.3) is related but different from the problem recently studied in the literature on “low-rank plus sparse representation”. In fact, the “low rank plus sparse” representation of (1.3) holds on the population covariance matrix, whereas the model considered by Candès et al. (2011), Chandrasekaran et al. (2010) considered such a representation on the data matrix. As there is no $\Sigma$ to estimate, their goal is limited to producing a low-rank plus sparse matrix decomposition of the data matrix, which corresponds to the identifiability issue of our study, and does not involve estimation or inference. In contrast, our ultimate goal is to estimate the population covariance matrices as well as the precision matrices. Our consistency result on $\Sigma_u$ demonstrates that the decomposition (1.3) is identifiable, and hence our results also shed the light of the “surprising phenomenon” of Candès et al. (2011) that one can separate fully a sparse matrix from a low-rank matrix when only the sum of these two components is available.

Moreover, note that in financial applications, the common factors $\mathbf{f}_t$ are sometimes known, as in Fama and French (1992). In other applications, however, the common factors may be unknown and need to be inferred. Interestingly, asymptotic analysis shows that as the dimensionality grows fast enough (relative to the sample size), the effect of estimating the unknown factors is negligible, and the covariance matrices of $\mathbf{Y}_t$ and $\mathbf{u}_t$ and their inverses can be estimated as if the factors were known (Fan et al. 2013).

We now divide our discussions into two cases: models with known factors and models with unknown factors.

### 1.2.1 Known Factors

When the factors are observable, one can estimate $\mathbf{B}$ by the ordinary least squares (OLS):

$$
\hat{\mathbf{B}} = (\hat{b}_1, ..., \hat{b}_N)',
$$

where

$$
\hat{b}_i = \arg \min_{b_i} \frac{1}{T} \sum_{t=1}^{T} (Y_{it} - b_i' \mathbf{f}_t)^2, \quad i = 1, ..., N.
$$
The residuals are obtained using the plug-in method: \( \hat{u}_{it} = Y_{it} - \hat{f}_t \).

Denote by \( \hat{u}_t = (\hat{u}_{1t}, \ldots, \hat{u}_{pt})' \). We then construct the residual covariance matrix as:

\[
S_u = \frac{1}{T} \sum_{t=1}^{T} \hat{u}_t \hat{u}_t' = (s_{u,ij}).
\]

Now we apply thresholding on \( S_u \). Define \( \hat{\Sigma}_u = (\hat{\sigma}_{ij})_{p \times p}, \hat{\sigma}_{ij} = \begin{cases} s_{u,ii}, & i = j; \\ \text{th}(s_{u,ij})I(|s_{u,ij}| \geq \tau_{ij}), & i \neq j. \end{cases} \) (1.5)

where \( \text{th}(\cdot) \) is a generalized shrinkage function of Antoniadis and Fan (2001), employed by Rothman et al. (2009) and Cai and Liu (2011), and \( \tau_{ij} > 0 \) is an entry-dependent threshold. In particular, the hard-thresholding rule \( \text{th}(x) = xI(|x| \geq \tau_{ij}) \) (Bickel and Levina [2008]) and the constant thresholding parameter \( \tau_{ij} = \delta \) are allowed. In practice, it is more desirable to have \( \tau_{ij} \) be entry-adaptive. An example of the threshold is

\[
\tau_{ij} = \omega_T (s_{u,ii}s_{u,jj})^{1/2}, \quad \text{for a given } \omega_T > 0 \quad (1.6)
\]

This corresponds to applying the thresholding with parameter \( \omega_T \) to the correlation matrix of \( S_u \). Cai and Liu (2011) discussed an alternative type of “adaptive threshold”. Moreover, we take \( \omega_T \) to be: some \( C > 0 \),

\[
\omega_T = C \sqrt{\frac{\log N}{T}},
\]

which is a proper threshold level to overrides the estimation errors.

The covariance matrix \( \text{Cov}(f_t) \) can be estimated by the sample covariance matrix

\[
\tilde{\text{Cov}}(f_t) = T^{-1}F'F - T^{-2}F'11'F,
\]

where \( F' = (f_1, \ldots, f_T) \), and \( 1 \) is a \( T \)-dimensional column vector of ones. Therefore we obtain a substitution estimator (Fan et al. [2011]):

\[
\hat{\Sigma} = \hat{B} \tilde{\text{Cov}}(f_t) \hat{B}' + \hat{\Sigma}_u. \quad (1.7)
\]

By the Sherman-Morrison-Woodbury formula,

\[
\Sigma^{-1} = \Sigma_u^{-1} - \Sigma_u^{-1} B (\text{Cov}(f_t)^{-1} + B'\Sigma_u^{-1}B)^{-1}B'\Sigma_u^{-1},
\]

which is estimated by

\[
\hat{\Sigma}^{-1} = \hat{\Sigma}_u^{-1} - \hat{\Sigma}_u^{-1} \hat{B} (\tilde{\text{Cov}}(f_t)^{-1} + \hat{B}'\hat{\Sigma}_u^{-1}\hat{B})^{-1}\hat{B}'\hat{\Sigma}_u^{-1}. \quad (1.8)
\]

1.2.2 Unknown Factors

When factors are unknown, Fan et al. [2013] proposed a nonparametric estimator of \( \Sigma \) based on the principal component analysis. Let \( \lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_N \) be the ordered eigenvalues of
the sample covariance matrix $S$ of $Y_t$ and $(\hat{\xi}_i)_{i=1}^N$ be their corresponding eigenvectors. Then the sample covariance has the following spectral decomposition:

$$S = \sum_{i=1}^K \hat{\lambda}_i \hat{\xi}_i \hat{\xi}_i^T + Q,$$

where $Q = \sum_{i=K+1}^N \hat{\lambda}_i \hat{\xi}_i \hat{\xi}_i^T$ is called “the principal orthogonal complement”, and $K$ is the number of common factors. We can apply thresholding on $Q$ as in (1.5) and (1.6). Denote the thresholded $Q$ by $\hat{\Sigma}_u$. Note that the threshold value in (1.6) now becomes, for some $C > 0$

$$\omega_T = C \left( \sqrt{\frac{\log N}{T}} + \frac{1}{\sqrt{N}} \right).$$

The estimator of $\Sigma$ is then defined as:

$$\hat{\Sigma}_K = \sum_{i=1}^K \hat{\lambda}_i \hat{\xi}_i \hat{\xi}_i^T + \hat{\Sigma}_u. \quad (1.9)$$

This estimator is called the Principal Orthogonal Complement thresholding (POET) estimator. It is obtained by thresholding the remaining components of the sample covariance matrix, after taking out the first $K$ principal components. One of the attractiveness of POET is that it is optimization-free, and hence is computationally appealing.

The POET (1.9) has an equivalent representation using a constrained least squares method. The least squares method seeks for $\hat{B} = (\hat{b}_1, \ldots, \hat{b}_N)^T$ and $\hat{F}^T = (\hat{f}_1, \ldots, \hat{f}_T)$ such that

$$(\hat{B}, \hat{F}) = \arg \min_{b_i \in \mathbb{R}^K, f_i \in \mathbb{R}^K} \sum_{i=1}^N \sum_{t=1}^T (Y_{it} - b_i' f_t)^2, \quad (1.10)$$

subject to the normalization

$$\frac{1}{T} \sum_{t=1}^T f_i f_t' = I_K, \quad \text{and} \quad \frac{1}{N} \sum_{i=1}^N b_i b_i' \text{ is diagonal.} \quad (1.11)$$

Putting it in a matrix form, the optimization problem can be written as

$$\arg \min_{B, F} \|Y' - BF'\|_F^2 \quad (1.12)$$

$$T^{-1} F' F = I_K, \quad B' B \text{ is diagonal.}$$

where $Y' = (Y_1, \ldots, Y_T)$ and $F' = (f_1, \ldots, f_T)$. For each given $F$, the least-squares estimator of $B$ is $\hat{B} = T^{-1} Y' F$, using the constraint (1.11) on the factors. Substituting this into (1.12), the objective function now becomes $\|Y' - T^{-1} Y' FF'\|_F^2 = \text{tr}[(I_T - T^{-1} FF')Y Y']$. The minimizer is now clear: the columns of $\hat{F}/\sqrt{T}$ are the eigenvectors corresponding to the $K$ largest eigenvalues of the $T \times T$ matrix $YY'$ and $B = T^{-1} Y' \hat{F}$ (see e.g., Stock and Watson (2002)). The residual is given by $\hat{u}_{it} = Y_{it} - \hat{b}_i \hat{f}_t$, based on which we can construct the sample covariance matrix of $\hat{\Sigma}_u$. Then apply the thresholding to
obtain \( \hat{\Sigma}_u \). The covariance of \( Y_t \) is then estimated by \( \hat{BB}^T + \hat{\Sigma}_u \). It can be proved that the estimator in (1.9) satisfies:
\[
\hat{\Sigma}_K = \hat{BB}^T + \hat{\Sigma}_u.
\]

Several methods have been proposed to consistently estimate the number of factors. For instance, Bai and Ng (2002) proposed to use:
\[
\hat{K} = \arg \min_{0 \leq k \leq M} \frac{1}{N} \text{tr} \left( \sum_{j=k+1}^{N} \hat{\lambda}_j \hat{\xi}_j \hat{\xi}_j^T \right) + \frac{k(N + T)}{NT} \log \left( \frac{NT}{N + T} \right),
\]
where \( M \) is a prescribed upper bound. The literature also includes, e.g., Ahn and Horenstein (2013); Alessi et al. (2010); Hallin and Liška (2007), Kapetanios (2010), among others. Numerical studies in Fan et al. (2013) showed that the covariance estimator is robust to over-estimating \( K \). Therefore, in practice, we can also choose a relatively large number for \( K \). Consistency can still be guaranteed.

### 1.2.3 Choosing the Threshold

Recall that the threshold value \( \omega_T \) depends on a user-specific constant \( C \). In practice, we need to choose \( C \) to maintain the positive definiteness of the estimated covariances for any given finite sample. To do so, write the error covariance estimator as \( \hat{\Sigma}_u(C) \), which depends on \( C \) via the threshold. We choose \( C \) in the range where \( \lambda_{\text{min}}(\hat{\Sigma}_u) > 0 \). Define
\[
C_{\text{min}} = \inf \{ C > 0 : \lambda_{\text{min}}(\hat{\Sigma}_u(M)) > 0, \quad \forall M > C \}. \tag{1.14}
\]

When \( C \) is sufficiently large, the estimator becomes diagonal, while its minimum eigenvalue must retain strictly positive. Thus, \( C_{\text{min}} \) is well defined and for all \( C > C_{\text{min}}, \hat{\Sigma}_u(C) \) is positive definite under finite sample. We can obtain \( C_{\text{min}} \) by solving \( \lambda_{\text{min}}(\hat{\Sigma}_u(C)) = 0, C \neq 0 \). We can also approximate \( C_{\text{min}} \) by plotting \( \lambda_{\text{min}}(\hat{\Sigma}_u(C)) \) as a function of \( C \), as illustrated in Figure 1.1. In practice, we can choose \( C \) in the range \( (C_{\text{min}} + \epsilon, M) \) for a small \( \epsilon \) and large enough \( M \). Choosing the threshold in a range to guarantee the finite-sample positive definiteness has also been previously suggested by Fryzlewicz (2013).

### 1.2.4 Asymptotic Results

Under regularity conditions (e.g., strong mixing, exponential-tail distributions), Fan et al. (2011, 2013) showed that for the error covariance estimator, assuming \( \omega_T^{-1} m_N = o(1) \),
\[
\| \hat{\Sigma}_u - \Sigma_u \|_2 = O_P \left( \omega_T^{-q} m_N \right),
\]
and
\[
\| \hat{\Sigma}_u^{-1} - \Sigma_u^{-1} \|_2 = O_P \left( \omega_T^{-q} m_N \right).
\]

Here \( q \in [0, 1) \) quantifies the level of sparsity as defined in (1.4), and \( \omega_T \) is given by: for some \( C > 0 \), when factors are known,
\[
\omega_T = \sqrt{\frac{\log N}{T}}.
\]
Figure 1.1 Minimum eigenvalue of $\hat{\Sigma}(C)$ as a function of $C$ for three choices of thresholding rules. Adapted from Fan et al. (2013).

\[
\begin{align*}
\omega_T &= \sqrt{\frac{\log N}{T}} + \frac{1}{\sqrt{N}}, \\
\|\hat{\Sigma} - \Sigma\|_2 &= \frac{1}{T} \sum_{t=1}^{T} (f_{1t} - \bar{f}_1)^2 - \text{Var}(f_{1t}) \cdot \|1_N1'_N\|_2,
\end{align*}
\]

when factors are known,

\[
\omega_T = \sqrt{\frac{\log N}{T} + \frac{1}{\sqrt{N}}}.
\]

The dimension $N$ is allowed to grow exponentially fast in $T$.

As for the convergence of $\hat{\Sigma}$, because the first $K$ eigenvalues of $\Sigma$ grow with $N$, one can hardly estimate $\Sigma$ with satisfactory accuracy in either the operator norm or the Frobenius norm. This problem arises not from the limitation of any estimation method, but is due to the nature of the high-dimensional factor model. We illustrate this in the following example.

**Example 1.2.1** Consider a simplified case where we know $b_i = (1, 0, ..., 0)'$ for each $i = 1, ..., N$, $\Sigma_0 = I$, and $\{f_{1t}\}_{t=1}^T$ are observable. Then when estimating $\Sigma$, we only need to estimate $\text{Cov}(f)$ using the sample covariance matrix $\hat{\text{Cov}}(f_1)$, and obtain an estimator for $\Sigma$:

\[
\hat{\Sigma} = B\hat{\text{Cov}}(f_1)B' + I.
\]

Simple calculations yield to

\[
\|\hat{\Sigma} - \Sigma\|_2 = \frac{1}{T} \sum_{t=1}^{T} (f_{1t} - \bar{f}_1)^2 - \text{Var}(f_{1t}) \cdot \|1_N1'_N\|_2,
\]

where $1_N$ denotes the $N$-dimensional column vector of ones with $\|1_N1'_N\|_2 = N$. Therefore, due to the central limit theorem employed on $\sqrt{T} \sum_{t=1}^{T} (f_{1t} - \bar{f}_1)^2 - \text{Var}(f_{1t})$, $\sqrt{T} \|\hat{\Sigma} - \Sigma\|_2$ is asymptotically normal. Hence $\|\hat{\Sigma} - \Sigma\|_2$ diverges if $N \gg \sqrt{T}$, even for such a simplified toy model.

As we have seen from the above example, the small error of estimating $\text{Var}(f_{1t})$ is substantially amplified due to the presence of $\|1_N1'_N\|_2$, the latter in fact determines the size of the largest eigenvalue of $\Sigma$. We further illustrate this phenomenon in the following example.

### Example 1.2.2
Consider an ideal case where we know the spectrum except for the first eigenvector of \( \Sigma \). Let \( \{ \lambda_j, \xi_j \}_{j=1}^N \) be the eigenvalues and vectors, and assume that the largest eigenvalue \( \lambda_1 \geq cN \) for some \( c > 0 \). Let \( \hat{\xi}_1 \) be the estimated first eigenvector and define the covariance estimator \( \hat{\Sigma} = \lambda_1 \hat{\xi}_1 \hat{\xi}_1^T + \sum_{j=2}^N \lambda_j \xi_j \xi_j^T \). Assume that \( \hat{\xi}_1 \) is a good estimator in the sense that \( \| \hat{\xi}_1 - \xi_1 \|_2^2 = O_P(T^{-1/2}) \), which can diverge when \( T = O(N^2) \).

On the other hand, we can estimate the precision matrix with a satisfactory rate under the operator norm. The intuition follows from the fact that \( \Sigma^{-1} \) has bounded eigenvalues. Let \( \hat{\Sigma}^{-1} \) denote the inverse of the POET estimator. Fan et al. (2013) showed that \( \hat{\Sigma}^{-1} \) has the same rate of convergence as that of \( \Sigma^{-1} \). Specifically,

\[
\| \hat{\Sigma}^{-1} - \Sigma^{-1} \|_2 = O_P \left( \omega_1^{-q} m_N \right).
\]

Comparing the rates of convergence of known and unknown factors, we see that when the common factors are unobservable, the rate of convergence has an additional term \( m_N / N^{(1-q)/2} \), coming from the impact of estimating the unknown factors. This impact vanishes when \( N \log N \gg T \), in which case the minimax rate as in Cai and Zhou (2010) is achieved. As \( N \) increases, more information about the common factors is collected, which results in more accurate estimation of the common factors \( \{ f_{it} \}_{t=1}^T \). Then the rates of convergence in both observable factor and unobservable factor cases are the same.

### 1.2.5 A numerical illustration
We now illustrate the above theoretical results by using a simple three-factor-model with a sparse error covariance matrix. The distribution of the data generating process is taken from Fan et al. (2013) (Section 7). Specifically, we simulated from a standard Fama-French three-factor model. The factor loadings are drawn from a trivariate normal distribution

\[
b_i = (b_{1i}, b_{2i}, b_{3i})' \sim N(\mu_B, \Sigma_B),
\]

and \( f_t \) follows a VAR(1) model

\[
f_t = \mu + \Phi f_{t-1} + \epsilon_t.
\]

To make the simulation more realistic, model parameters are calibrated from the real data on annualized returns of 100 industrial portfolios, obtained from the website of Kenneth French. As there are three common factors, the largest three eigenvalues of \( \Sigma \) are of the same order as \( \sum_{j=1}^N b_{j,1}^2, j = 1, 2, 3 \), which are approximately \( O(N) \), and grow linearly with \( N \).

We generate a sparse covariance matrix $\Sigma_u$ of the form:

$$\Sigma_u = D D \Sigma_0 D.$$ Here, $\Sigma_0$ is the error correlation matrix, and $D$ is the diagonal matrix of the standard deviations of the errors. We set $D = \text{diag}(\sigma_1, \ldots, \sigma_p)$, where each $\sigma_t$ is generated independently from a Gamma distribution $G(\alpha, \beta)$, and $\alpha$ and $\beta$ are chosen to match the sample mean and sample standard deviation of the errors. The off-diagonal entries of $\Sigma_0$ are generated independently from a normal distribution, with mean and standard deviation equal to the sample mean and sample standard deviation of the sample correlations among the estimated residuals. We then employ hard thresholding to make $\Sigma_0$ sparse, where the threshold is found as the smallest constant that provides the positive definiteness of $\Sigma_0$.

For the simulation, we fix $T = 300$, and let $N$ increase from 20 to 600 in increments of 20. We plot the averages and standard deviations of the distance from $\hat{\Sigma}$ and $S$ to the true covariance matrix $\Sigma$, under the norm $\|A\|_{\Sigma} = \frac{1}{N} \|\Sigma^{-1/2} A \Sigma^{-1/2} \|_F$ (recall that $S$ denotes the sample covariance). It is easy to see that

$$\|\hat{\Sigma} - \Sigma\|_{\Sigma} = \frac{1}{N} \|\Sigma^{-1/2} \hat{\Sigma} \Sigma^{-1/2} - I\|_F,$$

which resembles the relative errors. We also plot the means and standard deviations of the distances from $\hat{\Sigma}^{-1}$ and $S^{-1}$ to $\Sigma^{-1}$ under the spectral norm. Due to invertibility, the operator norm for $S^{-1}$ is plotted only up to $N = 280$.

We observe that the unobservable factor model performs just as well as the estimator if the factors are known. The cost of not knowing the factors is negligible when $N$ is large enough. As we can see from Figures 1.2, the impact decreases quickly. In addition, when estimating $\hat{\Sigma}^{-1}$, it is hard to distinguish the estimators with known and unknown factors, whose performances are quite stable compared to the sample covariance matrix. Intuitively, as the dimension increases, more information about the common factors becomes available, which helps infer the unknown factors. Indeed, as is shown in Bai (2003); Fan et al. (2014a), the principal components method can estimate the unknown factors at a rate:

$$\frac{1}{T} \sum_{t=1}^{T} \|\hat{f}_t - f_t\|^2 = O_P\left(\frac{1}{T^2} + \frac{1}{N}\right).$$

Hence as long as $N$ is relatively large, $\hat{f}_t$ can be estimated pretty accurately.

### 1.3 Precision Matrix Estimation and Graphical Models

Let $Y_1, \ldots, Y_T$ be $T$ data points from an $N$-dimensional random vector $Y = (Y_1, \ldots, Y_N)'$ with $Y \sim N_N(0, \Sigma)$. We denote the precision matrix $\Theta := \Sigma^{-1}$ and define an undirected
Figure 1.2 Averages of $N^{-1}||\Sigma^{-1/2}\hat{\Sigma}^{-1/2} - I||_F$ (left panel) and $||\hat{\Sigma}^{-1} - \Sigma^{-1}||_2$ (right panel) with known factors (solid red curve), unknown factors (solid blue curve), and sample covariance (dashed curve) over 200 simulations, as a function of the dimensionality $N$. Taken from Fan et al. (2013).

Graph $G = (V, E)$ based on the sparsity pattern of $\Theta$: Let $V = \{1, \ldots, N\}$ be the node set corresponding to the $N$ variables in $Y$, an edge $(j, k) \in E$ if and only if $\Theta_{jk} \neq 0$.

As we will explain in the next section, the graph $G$ describes the conditional independence relationships between $Y_1, \ldots, Y_N$: i.e., let $Y_{\setminus\{j,k\}} := \{Y_\ell : \ell \neq j,k\}$, then $Y_j$ is independent of $Y_k$ given $Y_{\setminus\{j,k\}}$ if and only if $(j,k) \notin E$.

In high dimensional settings where $N \gg T$, we assume that many entries of $\Theta$ are zero (or in another word, the graph $G$ is sparse). The problem of estimating large sparse precision matrix $\Theta$ is called covariance selection [Dempster 1972].

1.3.1 Column-wise Precision Matrix Estimation

A natural approach for estimating $\Theta$ is by penalizing the likelihood using the $L_1$-penalty (Banerjee et al. 2008; Friedman et al. 2008; Yuan and Lin 2007). To further reduce the estimation bias, Jalali et al. (2012); Lam and Fan (2009); Shen et al. (2012) propose either greedy algorithms or non-convex penalties for sparse precision matrix estimation. Under certain conditions, Ravikumar et al. (2011a); Rothman et al. (2008); Wainwright (2009); Zhao and Yu (2006); Zou (2006) study the theoretical properties of the penalized likelihood methods.

Another approach is to estimate $\Theta$ in a column-by-column fashion. For this, Yuan (2010) and Cai et al. (2011) propose the graphical Dantzig selector and CLIME respectively, which can be solved by linear programming. More recently, Liu and Luo (2012) and Sun and Zhang (2012) propose the SCIO and scaled-Lasso methods. Compared to the penalized likelihood
methods, the column-by-column estimation methods are computationally simpler and are more amenable to theoretical analysis.

In the rest of this chapter, we explain the main ideas of the column-by-column precision matrix estimation methods. We start with an introduction of notations. Let \( \nu := (\nu_1, \ldots, \nu_N)' \in \mathbb{R}^N \) and \( I(\cdot) \) be the indicator function, for \( 0 < q < \infty \), we define
\[
\|\nu\|_q := \left( \sum_{j=1}^N |\nu_j|^q \right)^{1/q}, \quad \|\nu\|_0 := \sum_{j=1}^N I(\nu_j \neq 0), \quad \text{and} \quad \|\nu\|_\infty := \max_j |\nu_j|.
\]

Let \( A \in \mathbb{R}^{N \times N} \) be a symmetric matrix and \( I, J \subset \{1, \ldots, N\} \) be two sets. Denote by \( A_{I,J} \) the submatrix of \( A \) with rows and columns indexed by \( I \) and \( J \). Let \( A_{j} \) be the \( j^{th} \) column of \( A \) and \( A_{\setminus j} \) be the submatrix of \( A \) with the \( j^{th} \) column \( A_{j} \) removed. We define the following matrix norms:
\[
\|A\|_q := \max_{\|v\|_q = 1} \|Av\|_q, \quad \|A\|_{\max} := \max_{j,k} |A_{jk}|, \quad \text{and} \quad \|A\|_F = \left( \sum_{j,k} |A_{jk}|^2 \right)^{1/2}.
\]

We also denote \( \Lambda_{\max}(A) \) and \( \Lambda_{\min}(A) \) to be the largest and smallest eigenvalues of \( A \).

The column-by-column precision matrix estimation method exploits the relationship between conditional distribution of multivariate Gaussian and linear regression. More specifically, let \( Y \sim \mathcal{N}(0, \Sigma) \), the conditional distribution of \( Y_j \) given \( Y_{\setminus j} \) satisfies
\[
Y_j \mid Y_{\setminus j} \sim \mathcal{N}_{N-1}(\Sigma_{(j,j)}(\Sigma_{(\setminus j,\setminus j)}\Sigma_{(j,j)})^{-1}Y_{\setminus j}, \Sigma_{(j,j)}(\Sigma_{(\setminus j,\setminus j)}\Sigma_{(j,j)})^{-1}\Sigma_{(j,j)}).
\]

Let \( \alpha_j := (\Sigma_{(\setminus j,\setminus j)})^{-1}\Sigma_{(j,j)} \in \mathbb{R}^{N-1} \) and \( \sigma_j^2 := \Sigma_{jj} - \Sigma_{(j,j)}(\Sigma_{(\setminus j,\setminus j)}\Sigma_{(j,j)})^{-1}\Sigma_{(j,j)} \). We have
\[
Y_j = \alpha_j'Y_{\setminus j} + \epsilon_j, \tag{1.15}
\]
where \( \epsilon_j \sim \mathcal{N}(0, \sigma_j^2) \) is independent of \( Y_{\setminus j} \). By the block matrix inversion formula, we have
\[
\Theta_{j,j} = (\text{Var}(\epsilon_j))^{-1} = \sigma_j^{-2}, \tag{1.16}
\]
\[
\Theta_{j,j,j} = -(\text{Var}(\epsilon_j))^{-1}\alpha_j = -\sigma_j^{-2}\alpha_j. \tag{1.17}
\]

Therefore, we can recover \( \Theta \) in a column by column manner by regressing \( Y_j \) on \( Y_{\setminus j} \) for \( j = 1, 2, \ldots, N \). For example, let \( Y \in \mathbb{R}^{T \times N} \) be the data matrix. We denote by \( \alpha_j := (\alpha_{j1}, \ldots, \alpha_{j(N-1)})' \in \mathbb{R}^{N-1} \). \[\text{Meinshausen and B"uhlmann (2006)}\] propose to estimate each \( \alpha_j \) by solving the Lasso regression:
\[
\hat{\alpha}_j = \arg \min_{\alpha_j \in \mathbb{R}^{N-1}} \frac{1}{2T} \|Y_{\setminus j} - Y_{\setminus j}\alpha_j\|_2^2 + \lambda_j \|\alpha_j\|_1,
\]
where \( \lambda_j \) is a tuning parameter. Once \( \hat{\alpha}_j \) is given, we get the neighborhood edges by reading out the nonzero coefficients of \( \hat{\alpha}_j \). The final graph estimate \( \hat{G} \) is obtained by either the “AND” or “OR” rule on combining the neighborhoods for all the \( N \) nodes. However, the neighborhood pursuit method of \[\text{Meinshausen and B"uhlmann (2006)}\] only estimates the graph \( G \) but cannot estimates the inverse covariance matrix \( \Theta \).
To estimate $\Theta$, Yuan (2010) proposes to estimate $\alpha_j$ by solving the Dantzig selector:

$$
\hat{\alpha}_j = \arg \min_{\alpha_j \in \mathbb{R}^{N-1}} \|\alpha_j\|_1 \text{ subject to } \|S_{\cdot j} - S_{\cdot j}^{\perp} \alpha_j\|_\infty \leq \gamma_j,
$$

where $S := T^{-1}YY'$ is the sample covariance matrix and $\gamma_j$ is a tuning parameter. Once $\hat{\alpha}_j$ is given, we can estimate $\sigma_j^2$ by $\hat{\sigma}_j^2 = [1 - 2\hat{\alpha}_j' S_{\cdot j} + \hat{\alpha}_j' S_{\cdot j}^{\perp} \hat{\alpha}_j]^{-1}$. We then get the estimator $\hat{\Theta}$ of $\Theta$ by plugging $\hat{\alpha}_j$ and $\hat{\sigma}_j$ into (1.16) and (1.17). Yuan (2010) analyzes the $L_1$-norm error $\|\hat{\Theta} - \Theta\|_1$ and shows its minimax optimality over certain model space.

In another work, Sun and Zhang (2012) propose to estimate $\alpha_j$ and $\sigma_j$ by solving a scaled-Lasso problem:

$$
\hat{b}_j, \hat{\sigma}_j = \arg \min_{b = (b_1, \ldots, b_N)', \sigma} \left\{ \frac{1}{2} b_j' S b_j + \sigma^2 + \lambda \sum_{k=1}^N S_{kk} |b_k| \right\} \text{ subject to } b_j = -1.
$$

Once $\hat{b}_j$ is obtained, $\alpha_j = \hat{b}_j$. Sun and Zhang (2012) provide the spectral-norm rate of convergence of the obtained precision matrix estimator. Cai et al. (2011) proposes the CLIME estimator, which directly estimates the $j$th column of $\Theta$ by solving

$$
\hat{\Theta}_{\cdot j} = \arg \min_{\Theta_{\cdot j}} \|\Theta_{\cdot j}\|_1 \text{ subject to } \|S \Theta_{\cdot j} - e_j\|_\infty \leq \delta_j, \text{ for } j = 1, \ldots, N,
$$

where $e_j$ is the $j$th canonical vector and $\delta_j$ is a tuning parameter. This optimization problem can be formulated into a linear program and has the potential to scale to large problems. In a closely related work of CLIME, Liu and Luo (2012) propose the SCIO estimator, which solves the $j$th column of $\Theta$ by

$$
\hat{\Theta}_{\cdot j} = \arg \min_{\Theta_{\cdot j}} \left\{ \frac{1}{2} \Theta_{\cdot j} S \Theta_{\cdot j} - e_j' \Theta_{\cdot j} + \lambda_j \|\Theta_{\cdot j}\|_1 \right\}.
$$

The SCIO estimator can be solved efficiently by the pathwise coordinate descent algorithm.

### 1.3.2 The Need of Tuning-Insensitive Procedures

Most of the methods described in the former section require choosing some tuning parameters that control the bias-variance tradeoff. Their theoretical justifications are usually built on some theoretical choices of tuning parameters that cannot be implemented in practice. For example, in the neighborhood pursuit method and the graphical Dantzig selector, the tuning parameter $\lambda_j$ and $\gamma_j$ depend on $\sigma_j^2$, which is unknown. The tuning parameters of the CLIME and SCIO depend on $\|\Theta\|_1$, which is unknown.

It remains an open problem on choosing the regularization parameter in a data-dependent way. Popular techniques include the $C_p$-statistic, AIC (Akaike information criterion), BIC (Bayesian information criterion), extended BIC (Chen and Chen 2008, 2012, Foygel and Drton 2010), RIC (Risk inflation criterion, Foster and George (1994)), cross validation, and covariance penalization (Efron 2004). Most of these methods require data splitting and have been only justified for low dimensional settings. Some progress has been made recently.
on developing likelihood-free regularization selection techniques, including permutation methods (Boos et al. 2009; Lysen 2009; Wu et al. 2007) and subsampling methods (Bach 2008; Ben-david et al. 2006; Lange et al. 2004; Meinshausen and Bühlmann 2010; Meinshausen and Bühlmann 2010) and subsampling methods (Bach 2008; Ben-david et al. 2006; Lange et al. 2004; Meinshausen and Bühlmann 2010; Meinshausen and Bühlmann 2010) also propose to select the tuning parameters using subsampling. However, these subsampling based methods are computationally expensive and are still lack of theoretical guarantees.

To handle the challenge of tuning parameter selection, we introduce a “tuning-insensitive” procedure for estimating the precision matrix of high dimensional Gaussian graphical models. Our method, named TIGER (Tuning-Insensitive Graph Estimation and Regression) is asymptotically tuning-free and only requires very few efforts to choose the regularization parameter in finite sample settings.

1.3.3 TIGER: A Tuning-Insensitive Approach for Optimal Precision Matrix Estimation

The main idea of the TIGER method is to estimate the precision matrix $\Theta$ in a column-by-column fashion. For each column, the computation is reduced to a sparse regression problem. This idea has been adopted by many methods described in Section 1.3.1. These methods differ from each other mainly by how they solve the sparse regression subproblem. Unlike these existing methods, the TIGER solves this sparse regression problem using the SQRT-Lasso (Belloni et al. 2012).

The SQRT-Lasso is a penalized optimization algorithm for solving high dimensional linear regression problems. For a linear regression problem $\tilde{Y} = \tilde{X}\beta + \epsilon$, where $\tilde{Y} \in \mathbb{R}^T$ is the response, $\tilde{X} \in \mathbb{R}^{T \times N}$ is the design matrix, $\beta \in \mathbb{R}^N$ is the vector of unknown coefficients, and $\epsilon \in \mathbb{R}^T$ is the noise vector. The SQRT-Lasso estimates $\beta$ by solving

$$\hat{\beta} = \arg \min_{\beta \in \mathbb{R}^N} \left\{ \frac{1}{\sqrt{T}} \| \tilde{Y} - \tilde{X}\beta \|_2 + \lambda \| \beta \|_1 \right\},$$

where $\lambda$ is the tuning parameter. It is shown in Belloni et al. (2012) that the choice of $\lambda$ for the SQRT-Lasso method is asymptotically universal and does not depend on any unknown parameter. In contrast, most of other methods, including the Lasso and Dantzig selector, rely heavily on a known standard deviation of the noise. Moreover, the SQRT-Lasso method achieves near oracle performance for the estimation of $\beta$.

In Liu and Wang (2012), they show that the objective function of the scaled-Lasso can be viewed as a variational upper bound of the SQRT-Lasso. Thus the TIGER method is essentially equivalent to the method in Sun and Zhang (2012). However, the SQRT-Lasso is more amenable to theoretical analysis and allows us to simultaneously establish optimal rates of convergence for the precision matrix estimation under many different norms.

Let $\Gamma := \text{diag}(S)$ be an $N$-dimensional diagonal matrix with the diagonal elements be the same as those in $S$. Conditioned on the observed data $Y_1, \ldots, Y_T$, we define

$$Z := (Z_1, \ldots, Z_N)' = Y\Gamma^{-1/2}.$$  

By (1.15), we have

$$Z_j\Gamma_{jj}^{1/2} = \alpha_j Z_j\Gamma_{jj}^{1/2} + \epsilon_j,$$  

(1.18)
We define
\[
\beta_j := \frac{1}{2} \Gamma^{-1/2}_{jj} \alpha_j \quad \text{and} \quad \tau^2_j = \sigma^2_j \Gamma^{-1}_{jj}.
\]
Therefore, we have
\[
Z_j = \beta_j' Z_j + \frac{1}{2} \Gamma^{-1/2}_{jj} \epsilon_j.
\] (1.19)
We define \( \hat{R} \) to be the sample correlation matrix:
\[
\hat{R} := (\text{diag}(S))^{-1/2} S (\text{diag}(S))^{-1/2}.
\]
Motivated by the model in (1.19), we propose the following precision matrix estimator.

**TIGER Algorithm**

For \( j = 1, \ldots, N \), we estimate the \( j \)th column of \( \Theta \) by solving:
\[
\hat{\beta}_j := \arg \min_{\beta_j \in \mathbb{R}^{N-1}} \left\{ \sqrt{T} \|Z_j - Z_j \hat{\beta}_j\|_2 + \lambda \|\beta_j\|_1 \right\}, \quad (1.20)
\]
\[
\hat{\tau}_j := \sqrt{T} \|Z_j - Z_j \hat{\beta}_j\|_2, \quad (1.21)
\]
\[
\hat{\Theta}_{jj} = \hat{\tau}_j^{-2} \hat{\Gamma}_{jj}^{-1} \quad \text{and} \quad \hat{\Theta}_{j,j} = -\hat{\tau}_j^{-2} \hat{\Gamma}_{jj}^{-1/2} \hat{\Gamma}^{-1/2}_{\cdot,j} \hat{\beta}_j.
\]

For the estimator in (1.20), \( \lambda \) is a tuning parameter. In the next section, we show that by choosing \( \lambda = \pi \sqrt{\frac{\log N}{2T}} \), the obtained estimator achieves the optimal rates of convergence in the asymptotic setting. Therefore, the TIGER procedure is asymptotically tuning free. For finite samples, we set
\[
\lambda := \zeta \pi \sqrt{\frac{\log N}{2T}}, \quad (1.22)
\]
with \( \zeta \) chosen from a range \([\sqrt{2}/\pi, 2]\). Since the choice of \( \zeta \) does not depend on any unknown parameters, we call the procedure *tuning-insensitive*. Practically, we found that simply setting \( \zeta = 1 \) gives satisfactory finite sample performance in most applications.

If a symmetric precision matrix estimate is preferred, we conduct the following correction:
\[
\tilde{\Theta}_{jk} = \min \{ \hat{\Theta}_{jk}, \hat{\Theta}_{kj} \} \quad \text{for all} \quad k \neq j.
\]
Another symmetrization method is
\[
\tilde{\Theta} = \frac{\Theta + \Theta'}{2}.
\]
As has been shown by Cai et al. (2011), if \( \hat{\Theta} \) is a good estimator, then \( \tilde{\Theta} \) will also be a good estimator: they achieve the same rates of convergence in the asymptotic settings.

Let \( Z \in \mathbb{R}^{T \times N} \) be the normalized data matrix, i.e., \( Z_{\cdot,j} = Y_{\cdot,j} \Sigma^{-1/2} \) for \( j = 1, \ldots, N \). An equivalent form of (1.20) and (1.21) is
\[
\hat{\beta}_j := \arg \min_{\beta_j \in \mathbb{R}^{N-1}} \left\{ \frac{1}{\sqrt{T}} \|Z_{\cdot,j} - Z_{\cdot,j} \beta_j\|_2 + \lambda \|\beta_j\|_1 \right\}, \quad (1.23)
\]
\[
\hat{\tau}_j := \frac{1}{\sqrt{T}} \|Z_{\cdot,j} - Z_{\cdot,j} \hat{\beta}_j\|_2, \quad (1.24)
\]
Once $\hat{\Theta}$ is estimated, we can also estimate the graph $\hat{G} := (V, \hat{E})$ based on the sparsity pattern of $\hat{\Theta}_{jk} \neq 0$.

### 1.3.4 Computation

Instead of directly solving (1.20) and (1.21), we consider the following optimization:

$$
\hat{\beta}_j, \hat{\tau}_j := \arg \min_{\beta_j \in \mathbb{R}^{N-1}, \tau_j \geq 0} \left\{ \frac{1 - 2\beta_j' \hat{R}_{\setminus j,j} + \beta_j' \hat{R}_{\setminus j,i \setminus j} \beta_j}{2\tau_j} + \frac{\tau_j}{2} + \lambda \| \beta_j \|_1 \right\},
$$

(1.25)

Liu and Wang (2012) show that the solution to (1.20) and (1.21) is the same as that to (1.25). Equation (1.25) is jointly convex with respect to $\beta_j$ and $\tau_j$ and can be solved by a coordinate-descent procedure. In the $t^{th}$ iteration, for a given $\tau_j^{(t)}$, we first solve a subproblem

$$
\beta_j^{(t+1)} := \arg \min_{\beta_j \in \mathbb{R}^{N-1}} \left\{ \frac{1 - 2\beta_j' \hat{R}_{\setminus j,j} + \beta_j' \hat{R}_{\setminus j,i \setminus j} \beta_j}{2\tau_j^{(t)}} + \lambda \| \beta_j \|_1 \right\},
$$

This is a Lasso problem and can be efficiently solved by the coordinate descent algorithm developed by Friedman et al. (2007). Once $\beta_j^{(t+1)}$ is obtained, we can calculate $\tau_j^{(t+1)}$ as

$$
\tau_j^{(t+1)} = \sqrt{1 - 2(\beta_j^{(t+1)})' \hat{R}_{\setminus j,j} + (\beta_j^{(t+1)})' \hat{R}_{\setminus j,i \setminus j} (\beta_j^{(t+1)})}.
$$

We iterate these two steps until the algorithm converges.

### 1.3.5 Theoretical Properties of TIGER

Liu and Wang (2012) establish the rates of convergence of the TIGER estimator $\hat{\Theta}$ to the true precision matrix $\Theta$ under different norms. In particular, let $\| \Theta \|_{\max} := \max_{jk} |\Theta_{jk}|$ and $\| \Theta \|_1 := \max_j \sum_k |\Theta_{jk}|$. Under the assumption that the condition number of $\Theta$ is bounded by a constant, they establish the element-wise sup-norm rate of convergence:

$$
\| \hat{\Theta} - \Theta \|_{\max} = O_P \left( \| \Theta \|_1 \sqrt{\frac{\log N}{T}} \right).
$$

(1.26)

Under mild conditions, the obtained rate in (1.26) is minimax optimal over the model class consisting of precision matrices with bounded condition numbers.

Let $I(\cdot)$ be the indicator function and $s := \sum_{j \neq k} I(\Theta_{jk} \neq 0)$ be the number of nonzero off-diagonal elements of $\Theta$. The result in (1.26) implies that the Frobenious norm error between $\hat{\Theta}$ and $\Theta$ satisfies:

$$
\| \hat{\Theta} - \Theta \|_F := \sqrt{\sum_{i,j} |(\hat{\Theta})_{ij} - \Theta_{ij}|^2} = O_P \left( \| \Theta \|_1 \sqrt{\frac{(N+s) \log N}{T}} \right).
$$

(1.27)

The rate in (1.27) is minimax optimal rate for the Frobenious norm error in the same model class consisting of precision matrices with bounded condition numbers.
Let $\|\Theta\|_2$ be the largest eigenvalue of $\Theta$ (i.e., $\|\Theta\|_2$ is the spectral norm of $\Theta$) and $k := \max_{i=1,\ldots,N} \sum_j I(\Theta_{ij} \neq 0)$. Liu and Wang [2012] also show that

$$
\|\hat{\Theta} - \Theta\|_2 \leq \|\hat{\Theta} - \Theta\|_1 = O_P \left( k\|\Theta\|_2 \sqrt{\frac{\log N}{T}} \right),
$$

(1.28)

This spectral norm rate in (1.28) is also minimax optimal over the same model class as before.

1.3.6 Applications to Modeling Stock Returns

We apply the TIGER method to explore a stock price dataset collected from Yahoo! Finance (finance.yahoo.com). More specifically, the daily closing prices were obtained for 452 stocks that were consistently in the S&P 500 index between January 1, 2003 through January 1, 2011. This gives us altogether 2,015 data points, each data point corresponds to the vector of closing prices on a trading day. With $S_{t,j}$ denoting the closing price of stock $j$ on day $t$, we consider the log-return variable $Y_{jt} = \log (S_{t,j}/S_{t-1,j})$ and build graphs over the indices $j$.

We Winsorize (or truncate) every stock so that its data points are within six times the mean absolute deviation from the sample average. In Figure 1.3(a) we show boxplots for 10 randomly chosen stocks. We see that the data contains outliers even after Winsorization; the reasons for these outliers includes splits in a stock, which increases the number of shares. It is known that the log-return data are heavy-tailed. To suitably apply the TIGER method, we Gaussianize the marginal distribution of the data by the normal-score transformation. In Figure 1.3(b) we compare the boxplots of the data before and after Gaussianization. We see the Gaussianization alleviates the effect of outliers.

In this analysis we use the subset of the data between January 1, 2003 to January 1, 2008, before the onset of the “financial crisis.” The 452 stocks are categorized into 10 Global Industry Classification Standard (GICS) sectors, including...
Consumer Discretionary (70 stocks), Consumer Staples (35 stocks), Energy (37 stocks), Financials (74 stocks), Health Care (46 stocks), Industrials (59 stocks), Information Technology (64 stocks), Materials (29 stocks), Telecommunications Services (6 stocks), and Utilities (32 stocks). It is expected that stocks from the same GICS sectors should tend to be clustered together in the estimated graph, since stocks from the same GICS sector tend to interact more with each other. In the graphs shown below, the nodes are colored according to the GICS sector of the corresponding stock.

In Figure 1.4 we visualize the estimated graph using the TIGER method on the data from January 1, 2003 to January 1, 2008. There are altogether $T = 1,257$ data points and $N = 452$ dimensions. Even though the TIGER procedure is asymptotically tuning-free, Liu and Wang (2012) show that a fine-tune step can further improve its finite sample performance. To fine-tune the tuning parameter, we adopt a variant of the stability selection method proposed by Meinshausen and Bühlmann (2010). As suggested in (1.22), we consider 10 equal-distance values of $\zeta$ chosen from a range $[\sqrt{2}/\pi, 2]$. We randomly sample 100 sub-datasets, each containing $B = \lfloor 10\sqrt{T} \rfloor = 320$ data points. On each of these 100 subsampled datasets, we estimate a TIGER graph for each tuning parameter. In the final graph shown in Figure 1.4, we use $\zeta = 1$ and an edge is present only if it appears more than 80 percent of the time among the 100 subsampled datasets (with all the singleton nodes removed).

From Figure 1.4, we see that stocks from the same GICS sectors are indeed close to each other in the graph. We refrain from drawing any hard conclusions about the effectiveness of the estimated TIGER graph—how it is used will depend on the application. One potential application of such a graph could be for portfolio optimization. When designing a portfolio, we may want to choose stocks with large graph distances to minimize the investment risk.

1.3.7 Applications to Genomic Network

As discussed before, an important application of precision matrix estimation is to estimate high dimensional graphical models. In this section we apply the TIGER method on a gene expression dataset to reconstruct the conditional independence graph of the expression levels of 39 genes.

This dataset includes 118 gene expression arrays from Arabidopsis thaliana originally appeared in Wille et al. (2004). Our analysis focuses on gene expression from 39 genes involved in two isoprenoid metabolic pathways: 16 from the mevalonate (MVA) pathway are located in the cytoplasm, 18 from the plastidial (MEP) pathway are located in the chloroplast, and 5 are located in the mitochondria. While the two pathways generally operate independently, crosstalk is known to happen (Wille et al. 2004). Our scientific goal is to recover the gene regulatory network, with special interest in crosstalk.

We first examine whether the data actually satisfies the Gaussian distribution assumption. In Figure 1.5 we plot the histogram and normal QQ plot of the expression levels of a gene named MECPS. From the histogram, we see the distribution is left-skewed compared to the Gaussian distribution. From the normal QQ plot, we see the empirical distribution has a heavier tail compared to Gaussian. To suitably apply the TIGER method on this dataset, we need to first transform the data so that its distribution is closer to Gaussian. Therefore, we Gaussianize the marginal expression values of each gene by converting them to the corresponding normal-scores. This is automatically done by the huge.npn function in the
We apply the TIGER on the transformed data using the default tuning parameter $\zeta = \sqrt{2/\pi}$. The estimated network is shown in Figure 1.6. We note that the estimated network is very sparse with only 44 edges. Prior investigations suggest that the connections from genes AACT1 and HMGR2 to gene MECPS indicate a primary source of the crosstalk between the MEP and MVA pathways and these edges are presented in the estimated network. MECPS is clearly a hub gene for this pathway.

For the MEP pathway, the genes DXPS2, DXR, MCT, CMK, HDR, and MECPS are connected as in the true metabolic pathway. Similarly, for the MVA pathway, the genes AACT2, HMGR2, MK, MPDC1, MPDC2, FPPS1 and FPP2 are closely connected. Our analysis suggests 11 cross-pathway links. This is consistent to previous investigation in Wille et al. (2004). This result suggests that there might exist rich inter-pathway crosstalks.
1.4 Financial Applications

1.4.1 Estimating Risks of Large Portfolios

Estimating and assessing the risk of a large portfolio is an important topic in financial econometrics and risk management. The risk of a given portfolio allocation vector $w_N$ is conveniently measured by $(w_N^t \Sigma w_N)^{1/2}$, in which $\Sigma$ is a volatility (covariance) matrix of the assets’ returns. Often multiple portfolio risks are at interests and hence it is essential to estimate the volatility matrix $\Sigma$. On the other hand, assets’ excess returns are often driven by a few common factors. Hence $\Sigma$ can be estimated via factor analysis as previously described in Section 1.

Let $\{Y_t\}_{t=1}^T$ be a strictly stationary time series of an $N \times 1$ vector of observed asset returns and $\Sigma = \text{Cov}(Y_t)$. We assume that $Y_t$ satisfies an approximate factor model:

$$Y_t = Bf_t + u_t, \ t \leq T,$$

where $B$ is an $N \times K$ matrix of factor loadings; $f_t$ is a $K \times 1$ vector of common factors, and $u_t$ is an $N \times 1$ vector of idiosyncratic error components. In contrast to $N$ and $T$, here $K$ is assumed to be fixed. The common factors may or may not be observable. For example, Fama and French (1993) identified three known factors that have successfully described the U.S. stock market. In addition, macroeconomic and financial market variables have been thought to capture systematic risks as observable factors. On the other hand, in an empirical study, Bai and Ng (2002) determined two unobservable factors for stocks traded on the New York Stock Exchange during 1994-1998.

As described in Section 1, the factor model implies the following decomposition of $\Sigma$:

$$\Sigma = B \text{Cov}(f_t) B' + \Sigma_u.$$

---

Figure 1.5 The histogram and normal QQ plots of the marginal expression levels of the gene MECPS. We see the data are not exactly Gaussian distributed. Adapted from Liu and Wang (2012).
Figure 1.6 The estimated gene networks of the Arabadopsis dataset. The within pathway edges are denoted by solid lines and between pathway edges are denoted by dashed lines. From [Liu and Wang (2012)].

In the case of observable factors, an estimator of \( \Sigma \) is constructed based on thresholding the covariance matrix of idiosyncratic errors, as in (1.7), denoted by \( \hat{\Sigma}_f \). In the case of unobservable factors, \( \Sigma \) can be estimated by POET as in (1.9), denoted by \( \hat{\Sigma}_P \). Because \( K \), the number of factors, might also be unknown, this estimator uses a data-driven number of factors \( \hat{K} \). Based on the factor analysis, the risk for a given portfolio \( w_N \) can be estimated by either \( \sqrt{w_N^t \hat{\Sigma}_f w_N} \) or \( \sqrt{w_N^t \hat{\Sigma}_P w_N} \), depending on whether \( f_t \) is observable.

**Estimating Minimum Variance Portfolio**

There are also many methods proposed to choose data-dependent portfolios. For instance, estimated portfolio vectors can arise when the ideal portfolio \( w_N \) depends on the inverse
of the large covariance $\Sigma$ (Markowitz (1952)), by consistently estimating $\Sigma^{-1}$. Studying the effects of estimating $\Sigma$ is also important for portfolio allocations. In these problems, estimation errors in estimating $\Sigma$ can have substantial implications (see discussions in El Karoui (2010)). For illustration, consider the following example of estimating the global minimum variance portfolio.

The global minimum variance portfolio is the solution to the problem:

$$w_{gmv}^N = \arg \min_{w} (w' \Sigma w), \quad \text{such that } w' e = 1$$

where $e = (1, \ldots, 1)$, yielding $w_{gmv}^N = \Sigma^{-1} e / (e' \Sigma^{-1} e)$. Although this portfolio does not belong to the efficient frontier, Jagannathan and Ma (2003) showed that its performance is comparable with those of other tangency portfolios.

The factor model yields a positive definite covariance estimator for $\Sigma$, which then leads to a data-dependent portfolio:

$$\hat{w}_{gmv}^N = \hat{\Sigma}^{-1} e / (e' \hat{\Sigma}^{-1} e)$$

$$\hat{\Sigma}^{-1} = \begin{cases} \hat{\Sigma}_f^{-1} & \text{known factors;} \\ \hat{\Sigma}_p^{-1} & \text{unknown factors} \end{cases}$$

It can be shown that $\hat{w}_{gmv}^N$ is $L_1$-consistent, in the sense that

$$\|\hat{w}_{gmv}^N - w_{gmv}^N\|_1 = o_P(1).$$

We refer to El Karoui (2010) and Ledoit and Wolf (2003) for further discussions on the effects of estimating large covariance matrices for portfolio selections.

Statistical Inference of the Risks

Confidence intervals of the true risk $w_N' \Sigma w_N$ can be constructed based on the estimated risk $\hat{w}_N' \hat{\Sigma} w_N$, where $\hat{\Sigma} = \hat{\Sigma}_f$ or $\hat{\Sigma}_p$, depending on whether the factors are known or not. Fan et al. (2014a) showed that, under some regularity conditions, respectively,

$$\left[ \text{Var} \left( \sum_{t=1}^T (\hat{w}_N' B f_t)^2 \right) \right]^{-1/2} T \hat{\Sigma} - \Sigma \rightarrow^d N(0, 1), \quad \hat{\Sigma} = \hat{\Sigma}_f \text{ or } \hat{\Sigma}_p,$$

where $\hat{w}_N$ is an $L_1$-consistent estimator of $w_N$.

An important implication is that the asymptotic variance is the same regardless of whether the factors are observable or not. Therefore, the impact of estimating the unknown factors is asymptotically negligible. In addition, it can also be shown that the asymptotic variance is slightly smaller than that of $w_N' Sw_N$, the sample covariance based risk estimator.

The asymptotic variance $\text{Var} \left( \sum_{t=1}^T (\hat{w}_N' B f_t)^2 \right)$ can be consistently estimated, using the heteroskedasticity and autocorrelation consistent covariance estimator of Newey and West (1987) based on the truncated sum of estimated autocovariance functions. Therefore, the above limiting distributions can be employed to assess the uncertainty of the estimated risks by, e.g., constructing asymptotic confidence intervals for $(w_N' \Sigma w_N)^{-1/2}$. Fan et al. (2014a) showed that the confidence interval is practically accurate even at the finite sample.
1.4.2 Large Panel Test of Factor Pricing Models

The content of this section is adapted from the recent work by Fan et al. (2014b), including graphs and tables. We consider a “factor-pricing model”, in which the excess return has the following decomposition:

\[ Y_{it} = \alpha_i + b_i'f_t + u_{it}, \quad i = 1, ..., N, \quad t = 1, ..., T. \] (1.31)

In this subsection, we shall focus on the case \( f_t \)'s are observable.

Let \( \alpha = (\alpha_1, ..., \alpha_N)' \) be the vector of intercepts for all \( N \) financial assets. The key implication from the multi-factor pricing theory is that \( \alpha \) should be zero, known as “mean-variance efficiency”, for any asset \( i \). An important question is then if such a pricing theory can be validated by empirical data, namely whether the null hypothesis

\[ H_0 : \alpha = 0, \] (1.32)

is consistent with empirical data.

Most of the existing tests to the problem (1.32) are based on the quadratic statistic \( W = \hat{\alpha}' \hat{\Sigma}_u^{-1} \hat{\alpha} \), where \( \hat{\alpha} \) is the OLS estimator for \( \alpha \), \( \hat{\Sigma}_u^{-1} \) is the estimated inverse of the error covariance, and \( a_T \) is a positive number that depends on the factors \( f_t \) only. Prominent examples are the test given by Gibbons et al. (1989), the GMM test in MacKinlay and Richardson (1991), and the likelihood ratio test in Beaulieu et al. (2007), all in quadratic forms. Recently, Pesaran and Yamagata (2012) studied the limiting theory of the normalized \( W \) assuming \( \hat{\Sigma}_u^{-1} \) were known. They also considered a quadratic test where \( \hat{\Sigma}_u^{-1} \) is replaced with its diagonalized matrix.

There are, however, two main challenges in the quadratic statistic \( W \). The first is that estimating \( \Sigma_u^{-1} \) is a challenging problem when \( N > T \), as described previously. Secondly, even though \( \Sigma_u^{-1} \) were known, this test suffers from a lower power in a high-dimensional-low-sample-size situation, as we now explain.

For simplicity, let us temporarily assume that \( \{u_t\}_{t=1}^T \) are i.i.d. Gaussian and \( \Sigma_u = \text{Cov}(u_t) \) is known, where \( u_t = (u_{1t}, ..., u_{Nt}) \). Under \( H_0 \), \( W \) is \( \chi^2_N \) distributed, with the critical value \( \chi^2_{N,q} \) which is of order \( N \), at significant level \( q \). The test has no power at all when \( T\alpha'\Sigma_u\alpha = o(N) \) or \( ||\alpha||^2 = o(N/T) \), assuming that \( \Sigma_u \) has bounded eigenvalues. This is not unusual for the high-dimension-low-sample-size situation we encounter, where there are thousands of assets to be tested over a relatively short time period (e.g. 60 monthly data). And it is especially the case when there are only a few significant alphas that arouse market inefficiency. By a similar argument, this problem can not be rescued by using any genuine quadratic statistic, which are powerful only when a non-negligible fraction of assets are mispriced. Indeed, the factor \( N \) above reflects the noise accumulation in estimating \( N \) parameters of \( \alpha \).

**High-dimensional Wald test**

Suppose \( \{u_t\} \) is i.i.d. \( N(0, \Sigma_u) \). Then as \( N, T \to \infty \), Pesaran and Yamagata (2012) showed that

\[ \frac{T \hat{\alpha}' \hat{\Sigma}_u^{-1} \hat{\alpha} - N}{\sqrt{2N}} \to^d \mathcal{N}(0, 1) \]
where \( a = 1 - \frac{1}{T} \sum_t f'_t (\frac{1}{T} \sum_t f_f f'_t)^{-1} \sum_t f_t \). This normalized Wald test is infeasible unless \( \Sigma_u^{-1} \) is consistently estimable. Under the sparse assumption of \( \Sigma_u \), this can be achieved by thresholding estimation as previously described. Let \( \hat{\Sigma}_u \) be the thresholding estimator, then a feasible high-dimensional Wald test is
\[
J_{sw} \equiv \frac{T a \hat{\alpha}' \hat{\Sigma}_u^{-1} \hat{\alpha} - N}{\sqrt{2N}}.
\]

With further technical arguments (see Fan et al. (2014b)), it can be shown that \( J_{sw} \to_d N(0, 1) \). Note that it is very technically involved to show that substituting \( \hat{\Sigma}_u \) for \( \Sigma_u \) is asymptotically negligible when \( N/T \to \infty \).

Power Enhancement Test

Traditional tests of factor pricing models are not powerful unless there are enough stocks that have non-vanishing alphas. Even if some individual assets are significantly mis-priced, their non-trivial contributions to the test statistic are insufficient to reject the null hypothesis. This problem can be resolved by introducing a power enhancement component (PEM) \( J_0 \) to the normalized Wald statistic \( J_{sw} \). The PEM \( J_0 \) is a screening statistic, designed to detect sparse alternatives with significant individual alphas.

Specifically, for some predetermined threshold value \( \delta_T > 0 \), define a set
\[
\hat{S} = \left\{ j : \frac{|\hat{\alpha}_j|}{\hat{\sigma}_j} > \delta_T, j = 1, \ldots, N \right\},
\]
where \( \hat{\alpha}_j \) is the OLS estimator and \( \hat{\sigma}_j^2 = \frac{1}{T} \sum_{t=1}^{T} \hat{u}_{jt}^2 / a \) is \( T \) times the estimated variance of \( \hat{\alpha}_j \), with \( \hat{u}_{jt} \) being the regression residuals. Denote a subvector of \( \hat{\alpha} \) by
\[
\hat{\alpha}_{\hat{S}} = (\hat{\alpha}_j : j \in \hat{S}),
\]
the screened-out alpha estimators, which can be interpreted as estimated alphas of mis-priced stocks. Let \( \hat{\Sigma}_{\hat{S}} \) be the submatrix of \( \hat{\Sigma}_u \) formed by the rows and columns whose indices are in \( \hat{S} \). So \( \hat{\Sigma}_{\hat{S}}/(Ta) \) is an estimated conditional covariance matrix of \( \hat{\alpha}_{\hat{S}} \), given the common factors and \( \hat{S} \).

With the above notation, we define the screening statistic as
\[
J_0 = \sqrt{NT a \hat{\alpha}_{\hat{S}}' \hat{\Sigma}_{\hat{S}}^{-1} \hat{\alpha}_{\hat{S}}}. \tag{1.34}
\]
The choice of \( \delta_T \) must suppress most of the noises, resulting in an empty set of \( \hat{S} \) under the null hypothesis. On the other hand, \( \delta_T \) cannot be too large to filter out important signals of alphas under the alternative. For this purpose, noting that the maximum noise level is \( O_P(\sqrt{\log N/T}) \), we let
\[
\delta_T = \log(\log T) \sqrt{\frac{\log N}{T}}.
\]
This is a high critism test. When \( N = 500 \) and \( T = 60 \), \( \delta_T = 3.514 \). With this choice of \( \delta_T \), if we define, for \( \sigma_j^2 = (\Sigma_u)_{jj} / (1 - E_f f_f' (Ef_f f_f')^{-1} Ef_f') \),
\[
S = \left\{ j : \frac{|\alpha_j|}{\sigma_j} > 2\delta_T, j = 1, \ldots, N \right\}, \tag{1.35}
\]
then under mild conditions, \( P(S \subset \hat{S}) \to 1 \), with some additional conditions, \( P(S = \hat{S}) \to 1 \), and \( \hat{\alpha}_S \) behaves like \( \alpha_S = (\alpha_j : j \in S) \).

The power enhancement test is then defined to be

\[
J_0 + J_{sw},
\]

whose detectable region is the union of those of \( J_0 \) and \( J_{sw} \). Note that under the null hypothesis, \( S = \emptyset \), so by the selection consistency, \( J_0 = 0 \) with probability approaching one. Thus the null distribution of the power enhancement test is that of \( J_{sw} \), which is standard normal. This means adding \( J_0 \) does not introduce asymptotic size distortion. On the other hand, since \( J_0 \geq 0 \), the power of \( J_0 + J_{sw} \) is always enhanced. Fan et al. (2014b) showed that the test is consistent against the alternative as any subset of:

\[
\{ \alpha \in \mathbb{R}^N : \max_{j \leq N} |\alpha_j| > 2\delta_T \max_{j \leq N} \sigma_j \} \cup \{ \alpha \in \mathbb{R}^N : \|\alpha\|^2 \gg (N \log N)/T \}.
\]

**Empirical Study**

We study monthly returns on all the S&P 500 constituents from the CRSP database for the period January 1980 to December 2012, during which a total of 1170 stocks have entered the index for our study. Testing of market efficiency is performed on a rolling window basis: for each month from December 1984 to December 2012. The test statistics are evaluated using the preceding 60 months’ returns (\( T = 60 \)). The panel at each testing month consists of stocks without missing observations in the past five years, which yields a cross-sectional dimension much larger than the time-series dimension (\( N > T \)). For testing months \( \tau = 12/1984, \ldots, 12/2012 \), we fit the Fama-French 3-factor model:

\[
r_{it} - r_{ft} = \alpha_i + \beta_{i,MKT}(MKT_t - r_{ft}) + \beta_{i,SMB}SMB_t + \beta_{i,HML}HML_t + u_{it},
\]

for \( i = 1, \ldots, N_\tau \) and \( t = \tau - 59, \ldots, \tau \), where \( r_{it} \) represents the return for stock \( i \) at month \( t \), \( r_{ft} \) the risk free rate, and \( MKT, SMB \) and \( HML \) constitute the FF-3 model’s market, size and value factors.

Table 1.4.2 summarizes descriptive statistics for different components and estimates in the model. On average, 618 stocks (which is more than 500 because we are recording stocks that
have ever become the constituents of the index) enter the panel of the regression during each five-year estimation window, of which 5.5 stocks are selected by \( \hat{S} \). The threshold \( \delta_T = \sqrt{\log N/T \log(\log T)} \) is about 0.45 on average, which changes as the panel size \( N \) changes for every window of estimation. The selected stocks have much larger alphas than other stocks do, as expected. As far as the signs of those alpha estimates are concerned, 61.84% of all the estimated alphas are positive, and 80.66% of all the selected alphas are positive. This indicates that market inefficiency is primarily contributed by stocks with extra returns, instead of a large portion of stocks with small alphas, demonstrating the sparse alternatives. In addition, we notice that the \( p \)-values of the thresholded Wald test \( J_{sw} \) is generally smaller than that of the test \( J_{wi} \) given by Pesaran and Yamagata (2012).

Figure 1.7  Dynamics of \( p \)-values and selected stocks (%), from Fan et al. (2014b)

We plot the running \( p \)-values of \( J_{wi} \), \( J_{sw} \) and the PEM test (augmented from \( J_{sw} \)) from December 1984 to December 2012. We also add the dynamics of the percentage of selected stocks (\( |\hat{S}|_0/N \)) to the plot, as shown in Figure 1.7. There is a strong negative correlation between the stock selection percentage and the \( p \)-values of these tests. This shows that the degree of market efficiency is influenced not only by the aggregation of alphas, but also by those extreme ones. We also observe that the \( p \)-value line of the PEM test lies beneath those of \( J_{sw} \) and \( J_{wi} \) tests as a result of enhanced power, and hence it captures several important market disruptions ignored by the latter two (e.g. Black Monday in 1987, collapse of Japanese...
bubble in late 1990, and the European sovereign debt crisis after 2010). Indeed, the null hypothesis of market efficiency is rejected by the PEM test at 5% level during almost all financial crisis, including major financial crisis such as Black Wednesday in 1992, Asian financial crisis in 1997, the financial crisis in 2008, which are also detected by $J_{sw}$ and $J_{wi}$ tests. For 30%, 60% and 72% of the study period, $J_{wi}$, $J_{sw}$ and the PEM test conclude that the market is inefficient respectively. The histograms of the $p$-values of the three test statistics are displayed in Figure 1.8.

### 1.5 Statistical Inference in Panel Data Models

#### 1.5.1 Efficient Estimation in Pure Factor Models

The sparse covariance estimation can also be employed to improve the estimation efficiency in factor models. Consider:

$$Y_{it} = b_i'f_t + u_{it}, \quad i \leq N, t \leq T,$$

In the model, only $Y_{it}$ is observable. In most literature, the factors and loadings are estimated via the principal components (PC) method, which solves a constraint minimization problem:

$$\min_{B, f_t} \sum_{t=1}^{T} (Y_t - Bf_t)'(Y_t - Bf_t)$$

subject to some identifiability constraints so that the solution is unique. The PC method does not incorporate the error covariance $\Sigma_u$, hence it essentially treats the error terms $u_{it}$ as cross-sectionally homoskedastic and uncorrelated. It is well known that under either cross-sectional heteroskedasticity or correlations, the PC method is not efficient. On the other hand, when $\Sigma_u$
is assumed to be sparse and estimated via thresholding, we can incorporate this covariance estimator into the estimation, and improve the estimation efficiency.

Weighted Principal Components

We can estimate the factors and loadings via the weighted least squares. For some \( N \times N \) positive definite weight matrix \( W \), solve the following optimization problem:

\[
\min_{B, \mathbf{f}} \sum_{t=1}^{T} (Y_t - B \mathbf{f}_t)' W (Y_t - B \mathbf{f}_t),
\]

subject to:

\[
\frac{1}{T} \sum_{t=1}^{T} \mathbf{f}_t \mathbf{f}_t' = I, \quad B'WB \text{ is diagonal}.
\]

Here \( W \) can be either stochastic or deterministic. When \( W \) is stochastic, it can be understood as a consistent estimator of some deterministic matrix. Solving the constrained optimization problem gives the WPC estimators:

\( \hat{b}_j \) and \( \hat{\mathbf{f}}_t \) are both \( K \times 1 \) vectors such that, the columns of the \( T \times K \) matrix \( \hat{\mathbf{F}} / \sqrt{T} = (\hat{\mathbf{f}}_1, ..., \hat{\mathbf{f}}_T)' / \sqrt{T} \) are the eigenvectors corresponding to the largest \( K \) eigenvalues of \( YY' \), and \( \hat{B} = T^{-1} Y' \hat{\mathbf{F}} = (\hat{b}_1, ..., \hat{b}_N)' \). This method is called weighted principal components (WPC, see Bai and Liao 2013), to distinguish from the traditional principal components (PC) method that uses \( W = I \). Note that PC does not encounter the problem of estimating large covariance matrices, and is not efficient when \( \{u_{it}\} \)'s are cross-sectionally correlated across \( i \).

Bai and Liao (2013) studied the inferential theory of the WPC estimators. In particular, they showed that for the estimated common component, as \( T, N \to \infty \),

\[
\frac{\hat{b}_i' \hat{\mathbf{f}}_t - b_i' \mathbf{f}_t}{(b_i' \hat{\Xi}_W b_i / N + \mathbf{f}_t' \hat{\Omega}_i \mathbf{f}_t / T)^{1/2}} \to^d N(0, 1).
\]

(1.37)

with \( \hat{\Xi}_W = \hat{\Sigma}_\lambda^{-1} B' W \hat{\Sigma}_\alpha W B \hat{\Sigma}_\lambda^{-1} / N \) and \( \hat{\Omega}_i = \text{Cov}(\mathbf{f}_t)^{-1} \Phi_i \text{Cov}(\mathbf{f}_t)^{-1} \), where

\[
\Phi_i = E(\mathbf{f}_t' \mathbf{f}_t u_{it}^2) + \sum_{i=1}^{\infty} E[(\mathbf{f}_t' \mathbf{f}_t' u_{it}^2 + \mathbf{f}_t' \mathbf{f}_t u_{it} u_{i+1})] u_{11} u_{i,1,1+1}.
\]

and \( \hat{\Sigma}_\lambda = \lim_{N \to \infty} B' W \hat{\Sigma}_\alpha W B \hat{\Sigma}_\lambda^{-1} / N \), assumed to exist. Note that although the factors and loadings are not individually identifiable, \( \hat{b}_i' \hat{\mathbf{f}}_t \) can consistently estimate the common component \( b_i' \mathbf{f}_t \), without introducing a rotational transformation.

Optimal Weight Matrix

There are three interesting choices for the weight matrix \( W \). The most commonly seen weight is the identity matrix, which leads to the regular PC estimator. The second choice of the weight matrix takes \( W = \text{diag}^{-1} \{\text{Var}(u_{11}), ..., \text{Var}(u_{Nt})\} \). The third choice is the optimal weight. Note that the asymptotic variance of the estimated common component in (1.37) depends on \( W \) only through

\[
\hat{\Xi}_W = \hat{\Sigma}_\lambda^{-1} B' W \hat{\Sigma}_\alpha W B \hat{\Sigma}_\lambda^{-1} / N.
\]
Approaches to High-Dimensional Covariance and Precision Matrix Estimation

Table 1.4: Three interesting choices of the weight matrix

<table>
<thead>
<tr>
<th></th>
<th>( W )</th>

<td>regular PC</td>
<td>( YY' )</td>
</tr>
<tr>
<td>heteroskedastic WPC</td>
<td>( Y \text{diag}(\Sigma_u)^{-1}Y' ) diag(\Sigma_u)^{-1}</td>
</tr>
<tr>
<td>efficient WPC</td>
<td>( Y\Sigma_u^{-1}Y' ) ( \Sigma_u^{-1} )</td>
</tr>
</tbody>
</table>

The estimated \( \hat{F}/\sqrt{T} \) is the eigenvectors of the largest \( r \) eigenvalues of \( YWY' \), and \( \hat{B} = T^{-1}Y'\hat{F} \).

It is straightforward to show that when \( W^* = \Sigma_u^{-1} \), the asymptotic variance is minimized, that is, for any positive definite matrix \( W \), \( \Xi W - \Xi W^* \) is semi-positive definite. In other words, the choice \( W = \Sigma_u^{-1} \) as the weight matrix of the WPC estimator yields the minimum asymptotic variance of the estimated common component.

Table 1.5.1 gives the estimators and the corresponding weight matrix. The heteroskedastic WPC uses \( W = I \), which takes into account the cross-sectional heteroskedasticity of \((u_{1t}, ..., u_{Nt})\), while the efficient WPC uses the optimal weight matrix \( \Sigma_u^{-1} \). Under the sparsity assumption, the optimal weight matrix can be estimated using the POET estimator as described in Section 3.

1.5.2 Panel Data Model with Interactive Effects

A closely related model is the panel data with a factor structure in the error term:

\[
Y_{it} = X_{it}^\prime \beta + \varepsilon_{it}, \quad \varepsilon_{it} = b_i'f_t + u_{it}, \quad i \leq N, t \leq T, \tag{1.38}
\]

where \( X_{it} \) is a \( d \times 1 \) vector of regressors; \( \beta \) is a \( d \times 1 \) vector of unknown coefficients. The regression noise \( \varepsilon_{it} \) has a factor structure with unknown loadings and factors, regarded as an interactive effect of the individual and time effects. In the model, the only observables are \((Y_{it}, X_{it})\). This model has been considered by many researchers, such as Ahn et al. (2001), Pesaran (2006), Bai (2009), Moon and Weidner (2010), and has broad applications in social sciences. For example, in the income studies, \( Y_{it} \) represents the income of individual \( i \) at age \( t \), \( X_{it} \) is a vector of observable characteristics that are associated with income. Here \( b_i \) represents a vector of unmeasured skills, such as innate ability, motivation, and hardworking; \( f_t \) is a vector of unobservable prices for the unmeasured skills, which can be time-varying.

The goal is to estimate the structural parameter \( \beta \), whose dimension is fixed. Because the regressor and factor can be correlated, simply regressing \( Y_{it} \) on \( X_{it} \) is not consistent. Let \( X_t = (x_{1t}, ..., x_{Nt})' \). The least squares estimator of \( \beta \) is

\[
\hat{\beta} = \arg \min_{\beta, f_t} \min_{i} \sum_{t=1}^{T} (Y_t - X_t'\beta - Bf_t)'W(Y_t - X_t'\beta - Bf_t), \tag{1.39}
\]

with a high-dimensional weight matrix \( W \). In particular, it allows a consistent estimator for \( \Sigma_u^{-1} \) as the optimal weight matrix, which takes into account both cross-sectional correlation and heteroskedasticity of \( u_{it} \) over \( i \). The minimization is subjected to the constraint \( \frac{1}{T} \sum_{t=1}^{T} f_t f_t' = I \) and \( B'WB \) being diagonal.
The estimated $\beta$ for each given $(B, \{f_t\})$ is simply

$$
\beta(B, \{f_t\}) = \left( \sum_{t=1}^{T} X_t' W X_t \right)^{-1} \sum_{t=1}^{T} X_t' W (Y_t - B f_t).
$$

On the other hand, given $\beta$, the variable $Y_t - X_t \beta$ has a factor structure. Hence the estimated $(B, f_t)$ are the weighted principal components estimators: let $X(\beta)$ be an $N \times T$ matrix $X(\beta) = (X_1 \beta, \ldots, X_T \beta)$. The columns of the $T \times r$ matrix $\hat{F}/\sqrt{T} = (\hat{f}_1, \ldots, \hat{f}_T)'/\sqrt{T}$ are the eigenvectors corresponding to the largest $r$ eigenvalues of $(Y' - X(\beta))' W (Y' - X(\beta))$, and $\hat{B} = T^{-1} (Y' - X(\beta)) \hat{F}$. Therefore, given $(B, f_t)$, we can estimate $\beta$, and given $\beta$, we can estimate $(B, f_t)$. So $\hat{\beta}$ can be simply obtained by iterations, with an initial value. The inversion $(\sum_{t=1}^{T} X_t' W X_t)^{-1}$ does not update during iterations.

**Optimal Weight Matrix**

To present the inferential theory of $\hat{\beta}$, additional notation is needed. Rearrange the design matrix

$$
Z = (X_{11}, \ldots, X_{1T}, X_{21}, \ldots, X_{2T}, \ldots, X_{N1}, \ldots, X_{NT})', \quad NT \times \text{dim}(\beta).
$$

Let

$$
A_W = \left[ W - WB (B'WB)^{-1} B'W \right] \otimes (I - F(F'F)^{-1} F'/T).
$$

Under regularity conditions, Bai and Liao (2013) showed that

$$
\sqrt{NT}(\hat{\beta} - \beta) \rightarrow^d \mathcal{N}(0, \Sigma_W),
$$

where, for $\Sigma_u = \text{Cov}(u_t)$,

$$
\Sigma_W = \text{plim}_{N,T \rightarrow \infty} \left( \frac{1}{NT} Z' A_W Z \right)^{-1} \frac{1}{NT} Z' A_W (\Sigma_u \otimes I) A_W Z \left( \frac{1}{NT} Z' A_W Z \right)^{-1}
$$

assuming the right hand side converges in probability.

It is not difficult to show that $W^* = \Sigma_u^{-1}$ is the optimal weight matrix, in the sense that $\Sigma_W - \Sigma_{W^*}$ is semi-positive definite for all positive definite weight matrix $W$. With $W = W^*$, the asymptotic variance of $\hat{\beta}$ is

$$
\Sigma_{W^*} = \text{plim}_{N,T \rightarrow \infty} \left( \frac{1}{NT} Z' A_{W^*} Z \right)^{-1}.
$$

Assuming $\Sigma_u$ to be sparse, one can estimate $W^*$ based on an initial estimator of $\beta$. Specifically, define $\hat{\beta}_0$ as in (1.39) with $W = I$, which is the estimator used in Bai (2009) and Moon and Weidner (2010). Apply the singular value decomposition to

$$
\frac{1}{T} \sum_{t=1}^{T} (Y_t - X_t \hat{\beta}_0)(Y_t - X_t \hat{\beta}_0)' = \sum_{i=1}^{N} \nu_i \xi_i \xi_i',
$$

where
where \((\nu_j, \xi_j)_{j=1}^N\) are the eigenvalues-eigenvectors of \(\frac{1}{T} \sum_{t=1}^T (Y_t - X_t \hat{\beta}_0)(Y_t - X_t \hat{\beta}_0)'\) in a decreasing order such that \(\nu_1 \geq \nu_2 \geq \ldots \geq \nu_N\). Then \(\hat{\Sigma}_u = (\hat{\Sigma}_{u,ij})_{N \times N}\),

\[
\hat{\Sigma}_{u,ij} = \begin{cases} \hat{R}_{ij}, & i = j \\ \theta_{ij}(\hat{R}_{ij}), & i \neq j \end{cases}, \quad \hat{R}_{ij} = \sum_{k=r+1}^N \nu_k \xi_{ki} \xi_{kj},
\]

where \(\theta_{ij}(\cdot)\) is the same thresholding function. The optimal weight matrix \(W^*\) can then be estimated by \(\hat{\Sigma}_u^{-1}\), and the resulting estimator \(\hat{\beta}\) achieves the asymptotic variance \(V_W^{-1}\).

### 1.5.3 Numerical illustrations

We present a simple numerical example to compare the weighted principal components with the popular methods in the literature. The idiosyncratic error terms are generated as follows:

Let \(\{\epsilon_{it}\}_{i \leq N, t \leq T}\) be i.i.d. \(\mathcal{N}(0, 1)\) in both \(t, i\). Let

\[
u_{1t} = \epsilon_{1t}, \quad \nu_{2t} = \epsilon_{2t} + a_1 \epsilon_{1t}, \quad \nu_{3t} = \epsilon_{3t} + a_2 \epsilon_{2t} + b_1 \epsilon_{1t},
\]

\[u_{4t} = \nu_{1t+1} + a_2 \nu_{1t} + b_1 \nu_{1t}, \quad u_{5t} = \nu_{1t} + \nu_{2t} - \nu_{1t}, \quad u_{6t} = \nu_{2t} + \nu_{2t} - \nu_{1t}, \quad u_{7t} = \nu_{2t} + \nu_{2t} - \nu_{1t}, \quad u_{8t} = \nu_{2t} + \nu_{2t} - \nu_{1t}, \quad u_{9t} = \nu_{2t} + \nu_{2t} - \nu_{1t}, \]

where \(\{a_i, b_i, \epsilon_i\}_{i=1}^N\) are i.i.d. \(\mathcal{N}(0, 1)\). Then \(\Sigma_u\) is a banded matrix, with both cross-sectional correlation and heteroskedasticity. Let the two factors \(\{f_{1t}, f_{2t}\}\) be i.i.d. \(\mathcal{N}(0, 1)\), and \(\{b_{1t}, b_{2t}\}_{i \leq N}\) be uniform on [0, 1].

### Pure Factor Model

Consider the pure factor model \(Y_{it} = b_{1t} f_{1t} + b_{2t} f_{2t} + u_{it}\). Estimators based on three weight matrices are compared: PC using \(W = \mathbf{I}\); HWPC using \(W = \text{diag}(\Sigma_u)^{-1}\) and EWPC using \(W = \Sigma_u^{-1}\). Here \(\Sigma_u\) is estimated using the POET estimator. The smallest canonical correlation (the larger the better) between the estimators and parameters are calculated, as an assessment of the estimation accuracy. The simulation is replicated for one hundred times, and the average canonical correlations are reported in Table 1.5.3. The mean squared error of the estimated common components are also compared.

We see that the estimation becomes more accurate when we increase the dimensionality. HWPC improves the regular PC, while the EWPC gives the best estimation results.

### Interactive Effects

Adding a regression term, we consider the panel data model with interactive effect: \(Y_{it} = x_{it}'\beta + b_{1t} f_{1t} + b_{2t} f_{2t} + u_{it}\), where the true \(\beta = (1, 3)'\). The regressors are generated to be dependent on \(f\) and \(b\):

\[
x_{it,1} = 2.5 b_{1t} f_{1t} - 0.2 b_{2t} f_{2t} + 1 + \eta_{it,1}, \quad x_{it,2} = b_{1t} f_{1t} - 2 b_{2t} f_{2t} + 1 + \eta_{it,2}
\]

where \(\eta_{it,1}\) and \(\eta_{it,2}\) are independent i.i.d. standard normal.

Both methods, PC (\textit{Bai} 2009) and WPC with \(W = \hat{\Sigma}_u^{-1}\), are carried out to estimate \(\hat{\beta}\) for the comparison. The simulation is replicated for one hundred times; results are summarized in Table 1.5.3. We see that both methods are almost unbiased, while the efficient WPC indeed has significantly smaller standard errors than the regular PC method in the panel model with interactive effects.

“Mean” is the average of the estimators; “Normalized SE” is the standard error of the estimators multiplied by $\sqrt{NT}$.

1.6 Conclusions

Large covariance and precision (inverse covariance) matrix estimations have become fundamental problems in multivariate analysis, which find applications in many fields, ranging from economics, finance to biology, social networks, and health sciences.

We introduce two efficient methods for estimating large covariance matrices and precision matrices. The introduced precision matrix estimator assumes the precision matrix to be sparse, which is immediately applicable for Gaussian graphical models. It is tuning-parameter insensitive, and simultaneously achieves the minimax optimal rates of convergence.
in precision matrix estimation under different matrix norms. On the other hand, the estimator based on factor analysis imposes a conditional sparsity assumption. Computationally, our procedures are significantly faster than existing methods. Both theoretical properties and numerical performances of these methods are presented and illustrated. In addition, we also discussed several financial applications of the proposed methods, including the risk management, testing high-dimensional factor pricing models. We also illustrate how the proposed covariance estimators can be used to improve statistical efficiency in estimating factor models and panel data models.
